CHAPTER 1

Introduction

1.1 Overview and aims

Traditionally the stratosphere was thought to respond passively to tropospheric forcing from below. However, modelling and observational evidence accrued over the last two decades has demonstrated that in some cases variability of the winter polar stratosphere can cause consistent circulation anomalies at the Earth's surface. This influence has been shown to be particularly strong following the rapid breakdown of the usual westerly winter stratospheric polar vortex; events known as sudden stratospheric warmings (SSWs).

Despite these advances, important issues remain as to the dynamics of SSWs and the stratosphere's influence on the troposphere. Most significantly:

- i. The dynamics of SSWs are not fully understood, in particular whether different mechanisms may be responsible for different types of event.
- ii. A mechanism for the stratosphere's influence on the troposphere is not well developed and is not understood why some types of stratospheric event appear to have different impacts on the troposphere than others.

These are significant long-standing issues, and providing a comprehensive solution is not possible here, but it is hoped that this thesis will go some way to

addressing them. A solution to these issues is not purely of theoretical interest, since it is necessary to understand the dynamics of these phenomena in order to simulate them in weather and climate prediction models; the ultimate aim being the development of more skillful forecasts. With an eye on this application, this thesis also aims to assess the predictability of the stratosphere and its connection to the troposphere.

The main original contributions of this thesis to the scientific literature are summarised below:

1. In **Chapter 3** a new method to diagnose stratospheric polar vortex variability and classify split and displaced vortex events is introduced and tested. This is the first semi-Lagrangian (or vortex-centric) method that can be easily and robustly applied to climate model simulations. Reanalysis data is then used to compare anomalies at the tropopause and the surface following the split and displaced vortex events. Although there may be some significant differences, the relatively short observational record hinders the statistical significance of these results.
2. In **Chapter 4** this method is applied to carry out the first multi-model comparison of split and displaced vortex events and their influence on the troposphere. It is found that there are a wide range of biases in the representation of the stratospheric polar vortex among models, at least some of which may be attributable to differences in vertical resolution. It is also shown that there are consistent differences between the tropospheric response to split and displaced vortex events among the models. These differences, and the large number of events studied, allows some inference of the mechanisms behind the different surface responses.
3. In **Chapter 5** the predictability of the stratospheric polar vortex is assessed in a stratosphere-resolving seasonal prediction system. Little skill is found in the prediction of the strength of Northern Hemisphere stratospheric polar vortex or the occurrence of split or displaced vortex events on seasonal

timescales. However, significant skill is found in the case of the Southern Hemisphere vortex. This enables the skillful prediction of interannual variability in ozone depletion beyond the lead time of previous forecasts. Furthermore, it is demonstrated that the stratospheric skill significantly enhances the skill of tropospheric forecasts several months ahead.

1.2 Relation to published work

Chapter 3 is largely based on a paper written by myself, Daniel Mitchell and Lesley Gray in *Geophysical Research Letters* [Seviour *et al.*, 2013], although the analysis has been significantly extended and re-written. The results in Chapter 5 on the Southern Hemisphere are based on a paper written by myself, Steven Hardiman, Lesley Gray, Neal Butchart, Craig MacLachlan, and Adam Scaife in *Journal of Climate* [?].

In both of these papers, all the writing is my own and I carried out all the analysis and produced the figures. However, I am of course very grateful for the constructive comments of my coauthors in the preparation of these papers as well as my reviewers; Harry Hendon (from the Centre for Australian Weather and Climate Research), and three of whom are anonymous.

1.3 Thesis structure

CHAPTER 1. INTRODUCTION

CHAPTER 2

Background

The stratosphere is the layer of the Earth's atmosphere which lies above the troposphere and is bounded by the tropopause below and the stratopause above. The height of the tropopause varies from about 15 km in altitude in the tropics to 7 km at high latitudes, while the stratopause lies at approximately 50 km. The defining feature of the stratosphere is a temperature gradient increasing with height (in contrast to the troposphere below), caused by the presence of ozone which absorbs ultraviolet radiation¹ and thereby heats the surrounding atmosphere. This temperature gradient makes the stratosphere stable against vertical convection and results in very different dynamical behaviour to the troposphere. In this chapter, our current understanding of the dynamics of the polar stratosphere are reviewed (Section 2.1), as well as the relationship between dynamics and polar stratospheric ozone depletion (Section 2.2), and stratosphere-troposphere coupling (Sections 2.3 and 2.4).

¹For this reason, the region of the stratosphere with the highest ozone concentrations is often called the "ozone layer".

2.1 Dynamics of the polar stratosphere

2.1.1 Zonal mean circulation

Each winter the polar regions descend into a polar night and the stratosphere cools by infrared radiation to space. This sets up a strong meridional temperature gradient which increases the vertical zonal wind shear in accordance with the thermal wind balance relation

$$\frac{\partial u_g}{\partial z} = -\frac{R}{fH} \frac{\partial T}{\partial y}, \quad (2.1)$$

where u_g is the geostrophic zonal velocity², $u_g = -f^{-1}\partial Z/\partial y$, Z is geopotential height, f is the Coriolis parameter, $f = 2\Omega \sin \phi$, and R is the specific gas constant. Here, a beta-plane geometry is used such that $f = f_0 + \beta y$, where $f_0 = f(\phi_0)$ and $\beta = 2\Omega a^{-1} \cos \phi_0$, a is the Earth's radius and ϕ_0 is a reference latitude. H is the scale height given by $H = RT_s/g$, where T_s is a reference temperature and g is the acceleration due to gravity. This equation relies on hydrostatic and geostrophic approximations but is approximately satisfied on seasonal timescales. Hence, the meridional temperature gradient decreasing from equator to pole results in a region of westerly winds surrounding the pole; this is known as the *stratospheric polar vortex*.³

Figure 2.1 shows zonal-mean zonal wind and temperature averaged over the boreal winter (December–February; DJF) and austral winter (July–August; JJA) using data from 1979–2010 from the ERA-Interim reanalysis (details in Section 3.3.1). In both cases the westerly vortex in the winter hemisphere can be seen along with a local minimum in temperature at the winter pole in the lower stratosphere. Weaker easterly winds are present in the summer hemisphere. The maximum strength of the polar vortex occurs at midlatitudes between 0.1–1 hPa in the mesosphere, and is stronger in the Southern Hemisphere (SH) with a maximum of 90 ms^{-1} than the Northern Hemisphere (NH) with a maximum of 50 ms^{-1} . The

²That is, the zonal wind balanced by pressure gradient forces.

³Alternative names for this which often appear in the literature are ‘polar night jet’ or ‘polar night vortex’. These names are not used here because the vortex persists outside of the polar night.

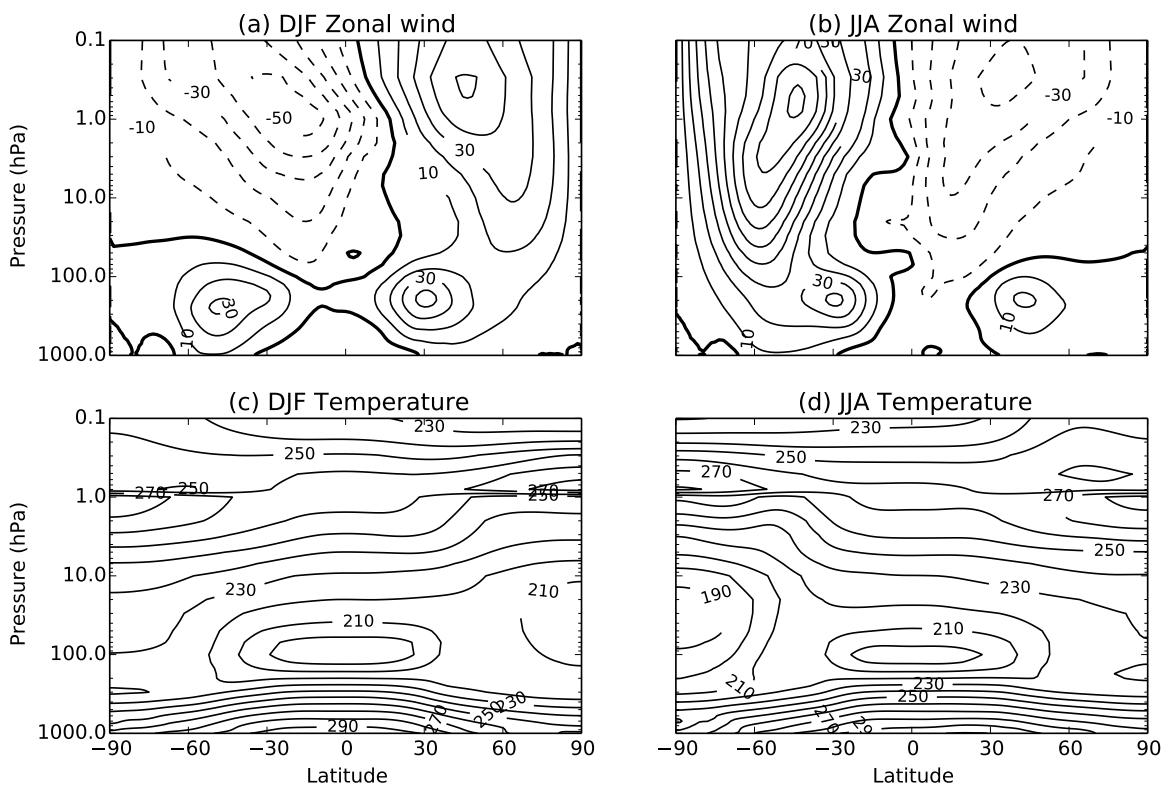

Figure 2.1: December-January (DJF) (a,c) and July-August (JJA) (b,d) averages of zonal-mean zonal wind (m s^{-1}) (a,b) and temperature (K) (c,d). Dashed contours represent negative values. Data is from the ERA-Interim reanalysis (1979-2010).

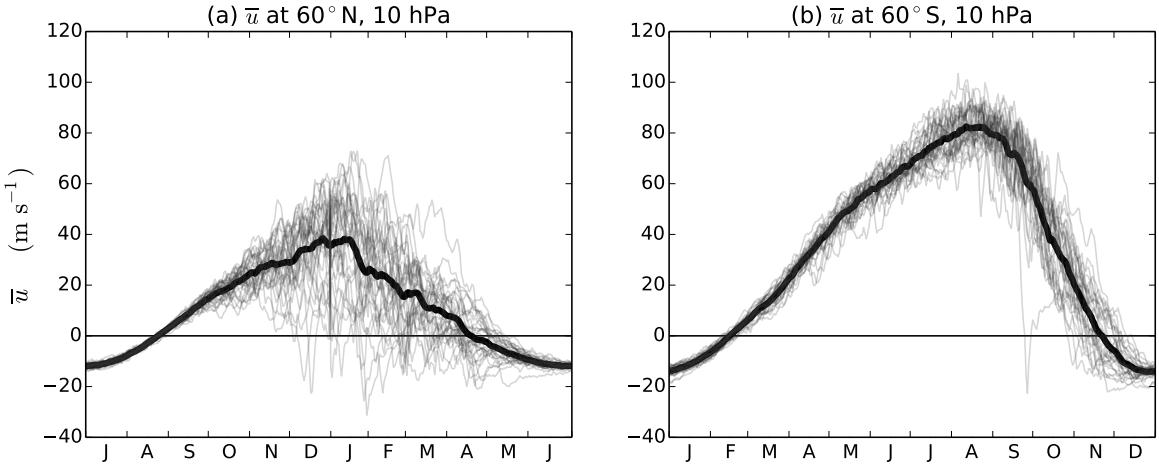

Figure 2.2: Seasonal cycle of NH (a) and SH (b) polar vortex strength, measured by \bar{u} at 60° N/S, 10 hPa. The annual mean is shown in a thick black line and individual years in thin grey lines. Both time series are centred on their respective winters. Data is from the ERA-Interim reanalysis (1979-2010).

winter polar stratosphere is also approximately 20 K colder in the SH than the NH.

The maximum strength of the vortex in the stratosphere occurs at approximately 60° N/S with little variation through the depth of the stratosphere. Figure 2.2 shows the annual cycle and variability of zonal-mean zonal wind at 10 hPa 60° N and 60° S. As well as being weaker on average than the SH, the winter NH stratospheric polar vortex can also be seen to be significantly more variable than the SH. There are a number of years in the NH for which \bar{u} becomes negative during the winter, but only one such year in the SH (these events are discussed further in Section 2.1.3). A further clear feature of both NH and SH is that variability during the summer is much less than that during winter. Also, the transition to summer easterlies (known as the final warming) occurs relatively earlier in the seasonal cycle in the NH than the SH. All these observations are due almost entirely to the influence of wave phenomena in the stratosphere, as described in the next section.

2.1.2 Waves in the stratosphere

2.1.2.1 Planetary waves

Large-scale Rossby or planetary waves⁴ play a vital role in the dynamics of the extratropical stratosphere. They mostly enter the stratosphere from the troposphere, where they are forced, for example, by air flow around topography, latent heat release, or nonlinear evolution of tropospheric eddies [Scinocca and Haynes, 1998]. These large-scale waves approximately satisfy the quasi-geostrophic (QG) approximation of hydrostatically balanced incompressible flow with low Rossby number, $\text{Ro} = U/f_0 L \ll 1$, where U and L are characteristic velocity and length scales respectively [Andrews et al., 1987]. Under this approximation and in the absence of friction, the following relation, known as the *quasi-geostrophic potential vorticity equation*, holds:

$$D_g q_g = f_0 \rho_0 \frac{\partial}{\partial z} \frac{\rho_0 Q}{\partial \theta_0 / \partial z}. \quad (2.2)$$

Where

$$D_g \equiv \frac{\partial}{\partial t} + u_g \frac{\partial}{\partial x} + v_g \frac{\partial}{\partial y}, \quad (2.3)$$

and

$$q_g = f_0 + \beta y - \frac{\partial v_g}{\partial x} + \frac{\partial u_g}{\partial y} + \rho_0^{-1} \frac{\partial}{\partial z} \left(\rho_0 f_0 \frac{\theta_e}{\partial \theta_0 / \partial z} \right), \quad (2.4)$$

is the quasi-geostrophic potential vorticity. Here, v_g is the geostrophic meridional velocity, $v_g = f^{-1} \partial Z / \partial x$, Q is the diabatic heating rate, ρ_0 is a reference density and θ_0 is a reference potential temperature, $\theta_0 = T_s(p_s/p)^\kappa$, where $p_s = 1000$ hPa, and $\kappa = R/c_p \approx 2/7$, where c_p is the specific heat capacity of air at constant pressure. θ_e represents the departure from θ_0 , and is assumed to be small in the sense that $|\partial \theta_e / \partial z| \ll |\partial \theta_0 / \partial z|$. An important consequence of Equation 2.2 is that q_g is conserved following the geostrophic wind for adiabatic flow ($Q = 0$), and therefore acts as a tracer.⁵

⁴Here, as is common in the stratospheric literature, “wave” is taken to mean any deviation from the zonal-mean state which not necessarily a physical structure in the usual meaning of the term.

⁵Throughout most of this thesis, Ertel’s potential vorticity, q , is used. This is defined by

$$q = \frac{1}{\rho} \zeta \cdot \nabla \theta,$$

In the case of approximately zonal flow $[\bar{u}(y, z), 0, 0]$, Equation 2.2 can be linearised to give

$$\left(\frac{\partial}{\partial t} + \bar{u} \frac{\partial}{\partial x} \right) q'_g + v' \frac{\partial \bar{q}_g}{\partial y} = f_0 \rho_0 \frac{\partial}{\partial z} \frac{\rho_0 Q'}{\partial \theta_0 / \partial z}, \quad (2.5)$$

where primes represent deviations from the zonal mean (e.g., $q_g = \bar{q}_g + q'_g$). It can be shown that Equation 2.5 supports wave-like solutions, with vertical propagation dependent upon the condition:

$$0 < \bar{u} - c < \bar{u}_c \equiv \beta(k^2 + l^2 + \epsilon/4H^2)^{-1}, \quad (2.6)$$

which is known as the *Charney-Drazin criterion* after *Charney and Drazin* [1961]. Here, c is the wave's zonal phase speed, k and l are the zonal and meridional wavenumbers respectively, and $\epsilon = f_0^2/N^2$, where $N^2 = H^{-1}Re^{-\kappa z/H}\partial\theta_0/\partial z$ is the static stability. In the case of waves whose phase is stationary with respect to the ground ($c = 0$), this simplifies to

$$0 < \bar{u} < \bar{u}_c. \quad (2.7)$$

It is therefore apparent that in order for planetary waves to propagate vertically (such as from the troposphere to the stratosphere), a westerly flow must be present that is not too strong. Additionally, this maximum speed is dependent on wavenumber, such that a lower wavenumber can propagate in a stronger westerly flow. While the assumptions here are not representative of the real atmosphere (such as purely zonal flow, and small deviations from the zonal mean), this criterion does capture the most important features of the relation between zonal assymmetries and the zonal flow, and similar relations can be found for more complex background states [*Andrews et al.*, 1987].

An important consequence of the Charney-Drazin criterion for stratospheric flow is that the strength of the stratospheric polar vortices shown in Figures 2.1

where ζ is the absolute vorticity. *Charney and Stern* [1962] showed that when the quasi-geostrophic approximation is valid

$$\left(\frac{\partial q}{\partial s} \right)_{\theta=\text{const.}} \approx \frac{1}{\rho_0} \frac{\partial \theta_0}{\partial z} \left(\frac{\partial q_g}{\partial s} \right)_{z=\text{const.}},$$

where $s = t, x$ or y . Hence, a similar conservation law as for q_g applies to q , which is conserved on isentropic (e.g., constant θ) surfaces.

2.1. DYNAMICS OF THE POLAR STRATOSPHERE

and 2.2 is often sufficient to exclude all but the lowest wavenumbers (typically zonal wavenumbers 1 and 2) from propagating upwards from the troposphere. Hence the length-scale of typical stratospheric zonal asymmetries is much larger than that of the troposphere.

When planetary waves reach a *critical surface*, where propagation is prohibited (for instance, a region where $\bar{u} = c$), the above linear analysis breaks down. In this scenario waves can “break”, imparting momentum onto the zonal flow. There is therefore a two-way interaction between the zonal flow and planetary waves; a phenomenon known as *wave-mean flow interaction*. Wave breaking was studied in an idealised two-dimensional model by *Stewartson [1978]* and *Warn and Warn [1978]*. They found momentum to be absorbed in a narrow *critical layer* close to the critical surface, with potential vorticity (PV) contours being irreversibly stretched and mixed in increasingly fine scales; a process known as a ‘potential enstrophy cascade’ [e.g., *Rhines and Holland, 1979*]. They also showed that the critical layer is initially absorbing, but becomes a reflecting surface after some time. Time varying results from a version of the Stewartson-Warn-Warn model from *Andrews et al. [1987]* are shown in Figure 2.3. Similar wave breaking behaviour was first observed in the real stratosphere by *McIntyre and Palmer [1983]* using isentropic maps of Ertel’s potential vorticity, including the irreversible deformation of PV contours of the kind shown in Figure 2.3.

A further effect of wave breaking is the induction of a *residual circulation*, $[0, \bar{v}^*, \bar{w}^*]$, where \bar{v}^* and \bar{w}^* are the transformed Eulerian-mean (TEM) meridional and vertical velocities given by

$$\bar{v}^* = \bar{v} - \frac{1}{\rho_0} \frac{\partial}{\partial z} \left(\frac{\rho_o \bar{v}' \theta'}{\partial \bar{\theta} / \partial z} \right), \quad (2.8)$$

$$\bar{w}^* = \bar{w} + \frac{1}{a \cos \phi} \frac{\partial}{\partial \phi} \left(\frac{\cos \phi \bar{v}' \theta'}{\partial \bar{\theta} / \partial z} \right), \quad (2.9)$$

which approximate the Lagrangian-mean circulation under time-averaged conditions [*Andrews and McIntyre, 1976; Dunkerton, 1978; Holton, 1990*]. Under the TEM

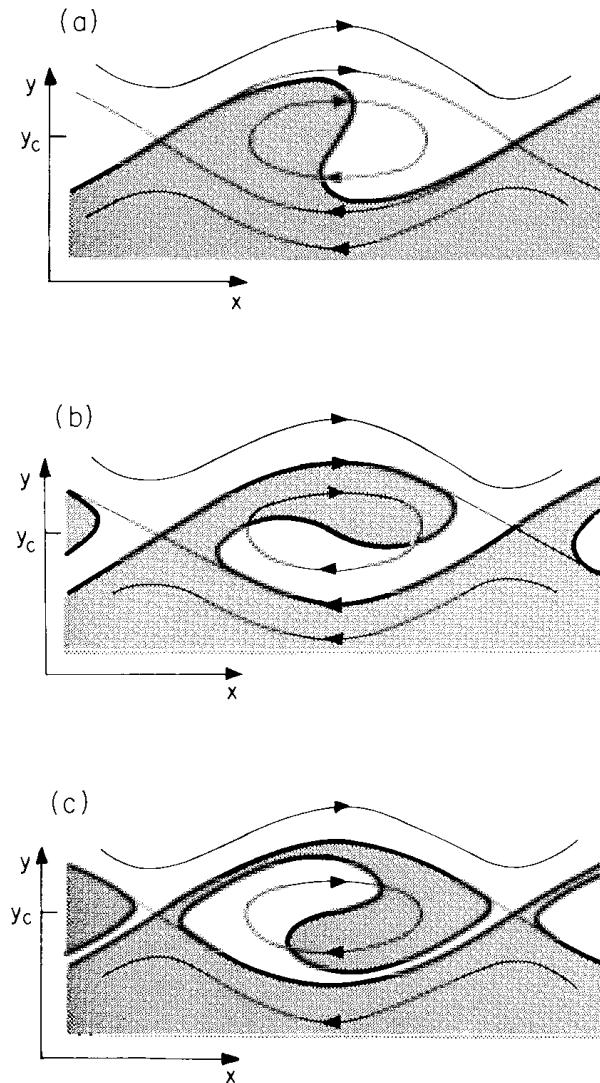

Figure 2.3: Stewartson-Warn-Warn time-dependent analytical solution of a Rossby wave nonlinear critical layer (time advancing in even steps from (a)-(b)-(c)). The flow is periodic in x and the y scale is greatly exaggerated and the initial critical line was at $y = y_c$. The thin lines indicate streamlines and lens shaped regions of closed streamlines are known as “Kelvin’s cats’ eyes”. The thick line shows the position of the absolute vorticity contour $\zeta = \zeta_c$, that initially lay along $y = y_c$ (in this barotropic model, the quasi-geostrophic potential vorticity, q_g , reduces to ζ). Hence, $\zeta < \zeta_c$ in the stippled region and $\zeta > \zeta_c$ in the unstippled region. In (a) it can be seen that $v > 0$ for most of the stippled region, indicating partial absorption, whereas in (b) and (c) $v \leq 0$ in the stippled region indicating reflection. Figure from [Andrews et al. \[1987\]](#).

formalism, the zonal momentum equation becomes

$$\frac{\partial \bar{u}}{\partial t} + \bar{v}^* \left(\frac{1}{a \cos \phi} \frac{\partial}{\partial \phi} (\bar{u} \cos \phi) - f \right) + \bar{w}^* \frac{\partial \bar{u}}{\partial z} = \frac{\nabla \cdot \mathbf{F}}{\rho_0 a \cos \phi} + \bar{X} \equiv \bar{\mathcal{F}} \quad (2.10)$$

where \bar{X} represents frictional terms and \mathbf{F} is the Eliassen-Palm (EP) flux with components

$$F^\phi = \rho_0 a \cos \phi \left(\frac{\partial \bar{u}}{\partial z} \frac{\overline{v' \theta'}}{\overline{\partial \theta / \partial z}} - \overline{v' u'} \right), \quad (2.11)$$

$$F^z = \rho_0 a \cos \phi \left(\left[f - \frac{1}{a \cos \phi} \frac{\partial}{\partial \phi} (\bar{u} \cos \phi) \right] \frac{\overline{v' \theta'}}{\overline{\partial \theta / \partial z}} - \overline{w' u'} \right). \quad (2.12)$$

\mathbf{F} can be interpreted as the flux of wave activity [Andrews *et al.*, 1987], and therefore $\nabla \cdot \mathbf{F} < 0$ (convergence) represents a dissipation of wave activity, as is the case in wave breaking. It can be seen that for a steady zonal flow ($\partial \bar{u} / \partial t = 0$) in the absence of wave driving ($\nabla \cdot \mathbf{F} = 0$) or friction ($\bar{X} = 0$), a solution of Equation (2.10) is $\bar{v}^* = 0, \bar{w}^* = 0$. However, in the presence of these forcing terms, a non-zero residual circulation will be induced. Climatologically, this circulation consists of upwelling in the tropics and poleward and downward motion in the extratropics; a pattern which forms a significant part of the Brewer-Dobson circulation⁶. The downward motion near the poles can be easily seen from Equation 2.10 in the steady case; since \bar{v}^* must become small near the poles (by conservation of mass), and $\partial \bar{u} / \partial z > 0$ in the polar vortex, if $\nabla \cdot \mathbf{F} < 0$, then $\bar{w}^* < 0$. It is observed that this circulation is strongest in the winter hemisphere due to the fact that more planetary waves can propagate and break in the winter westerly flow than the summer easterly flow (due to the Charney-Drazin criterion). Furthermore, during periods of enhanced wave breaking the residual circulation accelerates and there is more decent and adiabatic heating at high latitudes. This is important in the physical understanding of sudden stratospheric warming events, described in Section 2.1.3.

⁶Strictly, the Brewer-Dobson circulation represents the meridional transport of tracers, and so also involves two-way mixing (i.e. transport without net transfer of mass).

2.1.2.2 Gravity waves

Gravity waves are another type of atmospheric wave important in the dynamics of the polar stratosphere. These waves owe their existence to buoyancy restoring forces and can be generated by a number of processes such as air flow over topography (orographic gravity waves), convection or frontogenesis (non-orographic gravity waves). As with planetary waves, the differences in the land masses of the two hemispheres leads to orographic gravity wave activity being much greater in the NH. These waves make a net easterly contribution to the winter zonal flow [e.g., *Seviour et al., 2012*], and so act to enhance the residual circulation. Their typical length scales are much shorter than can be resolved in general circulation models or reanalyses, and so they are usually parametrised, appearing as the term \bar{X} in the zonal momentum equation (Equation 2.10).

Together, the Charney-Drazin criterion and the effects of planetary and gravity wave driving on the zonal flow can explain almost all hemispheric differences seen in Figures 2.1 and 2.2: Greater topography results in more planetary and gravity wave generation in the NH, both of which cause a net deceleration of the westerly polar vortex, thereby causing the NH vortex to be weaker than the SH. This also explains why the NH vortex is warmer than the SH, as the greater NH wave activity induces a stronger residual circulation with enhanced descent and adiabatic warming at high latitudes. Additionally, the strength of the SH vortex is such that it prohibits the vertical propagation of planetary waves from the troposphere throughout much of the winter, meaning that the SH vortex is less variable than the NH. Both hemispheres show very little variability in the summer easterly flow because planetary wave propagation is prohibited in this regime.

2.1.3 Sudden stratospheric warmings

First observed by *Scherhag [1952]* in radiosonde measurements over Berlin, the extreme events visible in Figure 2.2 whereby the winter circulation temporarily

2.1. DYNAMICS OF THE POLAR STRATOSPHERE

becomes easterly⁷ are known as sudden stratospheric warmings⁸ (SSWs). These events occur approximately 5-7 times per decade in the NH, but only one such event has been observed in the almost 60 year observational record in the SH (in 2002). They are called “warmings” because associated with the circulation reversal is a dramatic increase in temperature; as much as 50 K in the space of a few days in the midstratosphere.⁹

Initially these events were thought to result from either solar storms or baroclinic instability of the stratospheric polar vortex. However, *Matsuno* [1970, 1971] proposed a model of SSWs which relies on the influence of tropospherically forced planetary waves. This model (or modifications thereof) remains the most widely accepted dynamical view of SSWs at present. The mechanism proceeds as follows:

- i. A packet of enhanced planetary wave activity enters the stratosphere where it reaches a critical surface and breaks. This decelerates the zonal flow over a broader critical layer, and if strong enough causes it to reverse.
- ii. Hence a new, lower critical surface is formed (where $\bar{u} = 0$), and wave breaking occurs at this level. The process continues as the critical layer descends to the lower stratosphere.
- iii. At the same time, wave breaking induces an enhanced residual circulation with greater descent and adiabatic warming at high latitudes. If strong enough, this can act to reverse the meridional temperature gradient, further enhancing the easterly flow by thermal wind balance.
- iv. When the critical surface is close to the tropopause, planetary wave activity is essentially prohibited from entering the polar stratosphere. Radiative cooling

⁷For a discussion of more precise definitions of SSWs, see Section 3.1.

⁸Following *Butler et al.* [2014] it is suggested that the term “sudden stratospheric warming” is preferable to the common alternative “stratospheric sudden warming”. This is because there are other varieties of stratospheric warming (such as final warmings or Canadian warmings), but not other varieties of atmospheric sudden warming.

⁹A recent study [*Neef et al.*, 2014] has even suggested that SSWs have a sufficiently strong influence on the Earth’s angular momentum that they have a detectable influence on the length of the day.

to space then acts to cool the polar stratosphere and the vortex reforms over a period of approximately 2-4 weeks.

This mechanism takes place in an essentially zonal-mean framework. However, it has been observed that SSWs generally occur as either a split or displacement of the vortex, mostly depending (though not exclusively; see Section 3.1, [Waugh, 1997]) on whether wave-2 or wave-1 activity is dominant. An example of each of these events is shown in Figure 2.4. *Charlton and Polvani* [2007a] and *Matthewman et al.* [2009] studied the dynamics of these two types of events in reanalysis data and noted some differences. Most significantly, split vortex events were observed to occur near-barotropically, with two smaller vortices centred over Canada and Siberia throughout the depth of the stratosphere. On the other hand, displaced vortex events were observed to be more baroclinic, starting first in the upper stratosphere with a vortex centred over Canada, the centre of which rotates westward with height and is centred over Siberia in the lower stratosphere.

This different behaviour of split and displaced vortex events is not accounted for by the *Matsuno* [1970, 1971] model above, and so may suggest that other mechanisms are important in the generation of SSWs. For instance, *O'Neill and Pope* [1988] and *Scott and Dritschel* [2006] have suggested that SSWs can be generated by a cyclone-anticyclone interaction between the Aleutian high and the polar vortex. These studies showed that a smaller anticyclone can act to significantly distort the polar vortex, although such interactions are greatest for circulation ratios higher than are typically found in the polar stratosphere. Other studies have suggested that SSWs can arise through the resonant excitation of normal modes of the stratosphere by planetary waves [*Tung and Lindzen*, 1979]. Significantly, *Plumb* [1981] found that the planetary wave forcing need not be at exactly the resonant frequency of the mode (an occurrence which is probably unlikely), but that the two can be brought to resonance by a process known as nonlinear “self tuning”. *Smith* [1989] found behaviour suggestive of this process in simulations of a SSW. More recently, *Esler and Scott* [2005] and *Esler et al.* [2006] suggested that a relevant mode in the case of split vortex events is the barotropic mode of the atmosphere, which may explain the more barotropic nature of split vortex events.

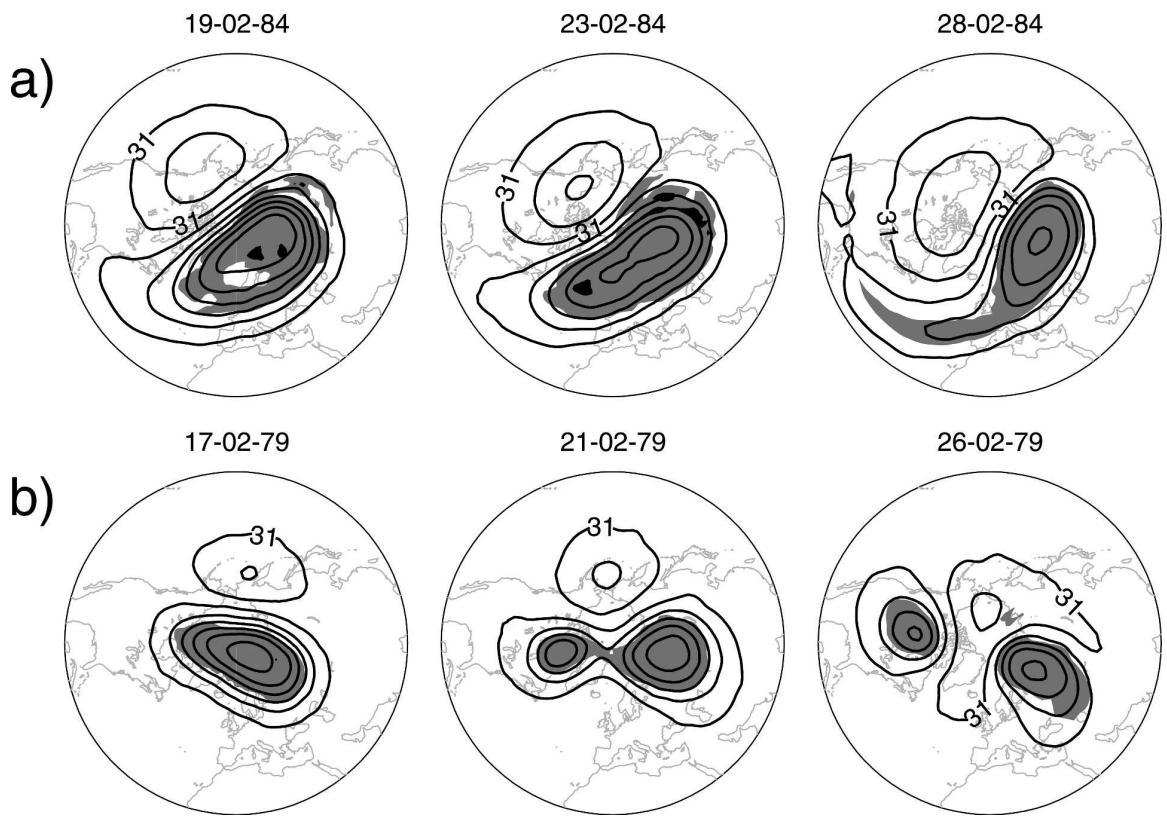

Figure 2.4: Polar stereographic plot of geopotential height (contours) on the 10 hPa pressure surface. Contour interval is 0.4 km, and shading shows potential vorticity greater than $4.0 \times 10^{-6} \text{ K kg}^{-1} \text{ m}^2 \text{ s}^{-1}$. (a) A vortex displacement type warming that occurred in February 1984. (b) A vortex splitting type warming that occurred in February 1979. Figure from [Charlton and Polvani \[2007b\]](#).

Further weight may be given to these mechanisms which do not rely on strong tropospheric forcing by the occurrence of the 2002 SH SSW, since this forcing is much weaker in the SH (several studies of the dynamics of this event can be found in the March 2005 special issue of *Journal of Atmospheric Sciences*). Indeed, *Esler et al.* [2006] provided evidence that this event may have been influenced by resonant excitation of the barotropic mode.

Overall, while significant advances in understanding the dynamics of SSWs have been made, several uncertainties remain. While tropospherically-driven wave activity is certainly an important factor, the roles (if any) of cyclone-anticyclone interactions or resonance are less certain. Moreover, it is not clear whether different mechanisms may be more or less important in driving split and displaced vortex events.

2.2 Polar stratospheric ozone depletion

The Antarctic ozone hole is a large region of severely depleted ozone concentrations in the lower-mid stratosphere which occurs during the austral spring. During its formation ozone may be completely lost at some altitudes. A similar, but much smaller depletion is observed in the NH [e.g., *Manney et al.*, 1997]. Following its discovery by *Farman et al.* [1985], a chemical and dynamical theory of the ozone hole was rapidly developed which largely attributes this rapid ozone depletion to the presence of anthropogenic chlorofluorocarbon (CFC) compounds [*McElroy et al.*, 1986; *Solomon et al.*, 1986]. This theory is summarised as follows:

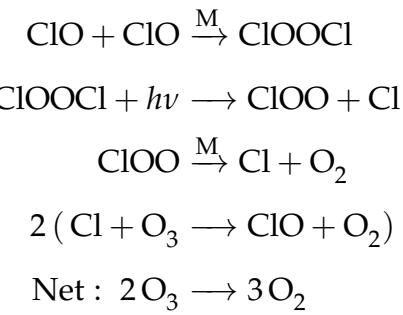

- i. The strong zonal winds of the stratospheric polar vortex act to confine air over the polar regions, with little mixing with midlatitudes [*Schoeberl and Hartmann, 1991*]. This results in a region of very cold temperatures which allow the formation of polar stratospheric clouds (PSCs; these require temperatures below approximately 195 K to form [*Newman, 2010*]).
- ii. Heterogeneous chemical reactions can take place on the surface of PSCs which act to convert ‘reservoir’ chlorine species such as ClONO₂ and HCl

2.2. POLAR STRATOSPHERIC OZONE DEPLETION

into forms that can accelerate ozone depletion, for instance [*Solomon et al.*, 1986]:

- iii. As sunlight returns to the vortex region in spring, Cl_2 is rapidly photolysed and reacts with oxygen to form ClO . This can then catalytically destroy ozone through a reaction sequence such as the following suggested by *Molina and Molina* [1987]:

where ν is the frequency of light, h is Planck's constant, and M a third body (necessary for conservation of momentum). Several other reaction sequences are also possible, for instance involving Bromine species.

- iv. A further effect of PSCs is that their particles fall out of the stratosphere and thereby remove nitrogen compounds (NO_x) from the polar lower stratosphere [*Toon et al.*, 1986]. This has the effect of further enhancing ozone depletion because these compounds can react with ClO to form reservoir compounds. For instance through the reaction:

- v. After some time, radiative heating of the stratosphere is sufficient to prevent the formation of PSCs, so ozone depletion halts. This heating is further accelerated by the increased wave breaking in the polar stratosphere which can take place as the vortex weakens (due to the Charney-Drazin criterion) and thereby induce an enhanced residual circulation. Following the final breakdown of the vortex and transition to easterlies (final warming), the ozone-depleted air is mixed to lower latitudes.

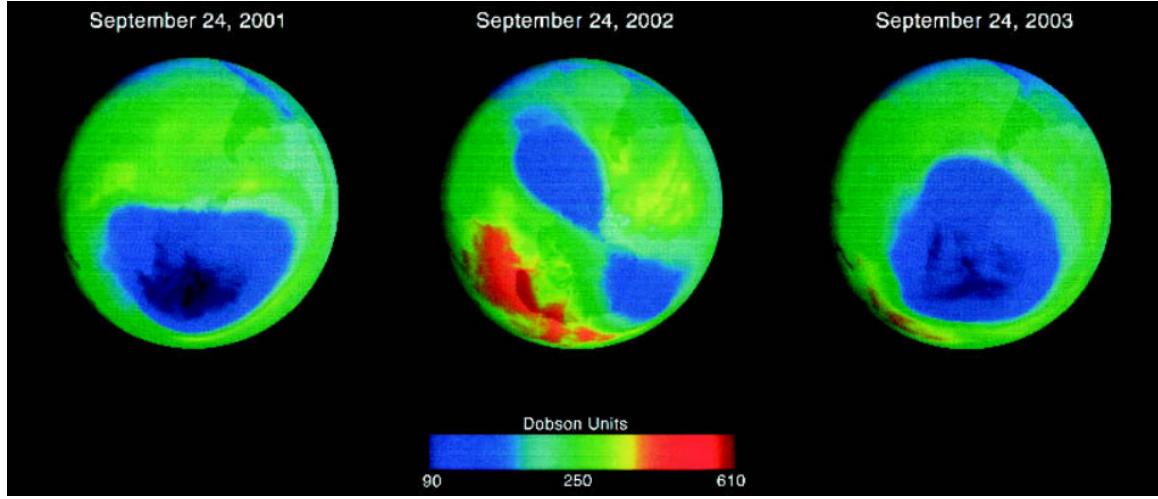

Figure 2.5: Comparison of the (middle) first split ozone hole on record (2002) and (left) the Antarctic ozone hole at the same time one year earlier (2001) and (right) one year later (2003). The hole is dark blue and magenta. In 2001, the ozone layer thinning over Antarctica reached $26.5 \times 10^6 \text{ km}^2$, larger than the size of the entire North American continent. Due to higher Antarctic winter temperatures, the 2002 “hole” seems to be about 40% smaller. In 2003, Antarctic winter temperatures returned to normal and the ozone hole returned to its usual state. Figure from *Shepherd et al.* [2005].

Importantly, the stratospheric dynamics described in Section 2.1, play an important role in ozone depletion. As discussed in Section 2.1.2.1, wave breaking in the stratosphere acts to drive a residual circulation, with descent and adiabatic warming over the pole. Enhanced descent and warming over the pole acts to inhibit the formation of PSCs which are necessary for the heterogeneous chemical reactions which cause ozone depletion.

It is this greater wave activity in the NH than that explains why ozone depletion is much greater in the SH. Moreover, it has been demonstrated in interannual variability in wave driving (as measured by $\nabla \cdot \mathbf{F}$) explains most of the interannual variability of ozone depletion through this mechanism [*Salby et al.*, 2012]. In the extreme event of SSWs, the ozone hole can be severely disrupted. This can be seen in Figure 2.5, where a clear split of the ozone hole is visible during the 2002 SH SSW, which contrasts with the more zonally symmetric distributions seen at the same times in 2001 and 2003. The magnitude of the 2002 ozone hole can also be seen to be reduced; a result of an enhanced residual circulation causing warmer stratospheric temperatures. The importance of this link between dynamics and

chemistry for predicting interannual variability in ozone depletion is discussed further in Sections 5.4.2 and 5.5.

2.3 Annular modes

Before discussing the influence of the stratosphere on the troposphere, it is necessary to introduce the concept of the annular modes which are often analysed in studies on this topic (as well as in this thesis). The northern and southern annular modes (NAM and SAM) are the leading modes of large-scale variability in the two hemispheres [*Baldwin and Dunkerton, 1999; Thompson and Wallace, 2000; Thompson et al., 2000; Limpasuvan and Hartmann, 1999, 2000*]. They are commonly defined to be the leading empirical orthogonal function (EOF)¹⁰ of extratropical monthly-mean geopotential height calculated at each pressure surface [e.g., *Baldwin and Dunkerton, 1999*], with an index of the respective principal component or the projection of daily data onto the EOF pattern. *Baldwin and Thompson [2009]* introduced an alternative using zonal-mean geopotential height, which is therefore less computationally expensive to calculate. The annular modes at the surface are also often calculated from mean sea-level pressure [e.g., *Gong and Wang, 1999*], where they may also be referred to as the Arctic and Antarctic oscillation (although in this thesis, the terms ‘surface NAM/SAM’ are used).

Figure 2.6 shows linear regressions of zonal-mean geostrophic winds and lower tropospheric geopotential height on the NAM and SAM indices as defined by *Thompson and Wallace [2000]*. It can be seen that the near-surface NAM structure is more zonally asymmetric than the SAM, with centres of action located over the Atlantic and Pacific oceans, and the SAM having a more clearly ‘annular’ structure. The vertical structure of the NAM and SAM appears near barotropic, although with a slight poleward tilt with height. The magnitude of the zonal wind signature also increases with height, reaching a maximum in the upper troposphere/lower stratosphere.

¹⁰EOFs are the eigenvectors of the spatially weighted covariance matrix of a variable. EOF analysis is also known as principal component analysis [*Wilks, 2006*].

Despite this near-barotropic appearance, annular mode variability has quite different physical interpretations in the troposphere and stratosphere. Stratospheric variability is associated with approximately zonally symmetric strengthening and weakening of the stratospheric polar vortex, while tropospheric variability is more closely associated with meridional shifts in the eddy-driven jets. Moreover, stratospheric annular mode variability is largely confined to winter, while tropospheric variability has a much less pronounced seasonal cycle.

It can be seen from Figure 2.6(d) that the Atlantic centre of action of the NAM resembles the familiar North Atlantic Oscillation (NAO) pattern. Indeed, the surface NAM and NAO have been observed to be highly correlated [*Ambaum et al., 2001*]. This has led to some debate as to whether the NAM represents a physical mode of variability of which the NAO is just a regional manifestation, or the NAM is simply a statistical artifact of more regional variability. This point is addressed in Section 4.4.2.

2.4 Stratosphere-troposphere coupling

So far this chapter has dealt with the dynamics of the stratosphere as responding passively to tropospheric forcing from below. Indeed, this was the dominant view until the last two decades [e.g., *Andrews et al., 1987*]. However observational evidence supported by modelling studies and some theoretical arguments, have now provided evidence that variability of the polar stratosphere can significantly influence tropospheric weather and climate. This section reviews this evidence.

2.4.1 Observational evidence

The accumulation of observational evidence for a two-way dynamical link between the polar stratosphere and the troposphere began in the early 1990s. *Kodera et al. [1990]* found that the strength of the NH upper stratospheric polar vortex during December was correlated with the strength of the tropospheric eddy-driven jet in February. However, they did not investigate the mechanism for this relation, and suggested it may be radiative. Further evidence was provided by

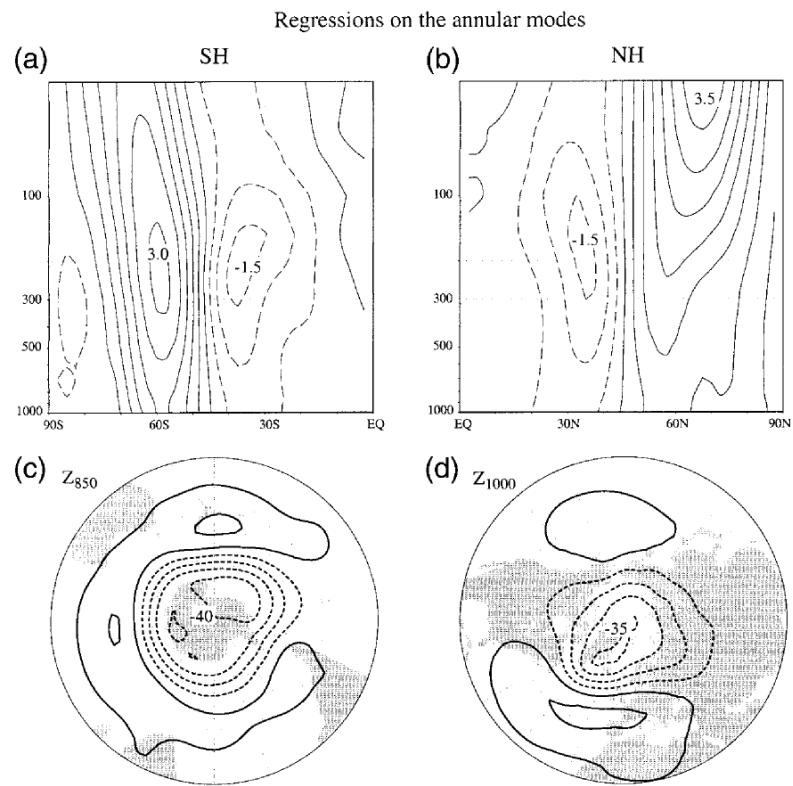

Figure 2.6: (top) Zonal-mean geostrophic wind and (bottom) lower-tropospheric geopotential height regressed on the standardised indices of the annular modes (the AO and its SH counterpart) based upon monthly data, Jan 1958–Dec 1997. Left panels are for the SH, right panels are for the NH. Units are m s^{-1} (top) and $\text{m per std dev of the respective index time series}$ (bottom). Contour intervals are 10 m ($-15, -5, 5, \dots$) for geopotential height and 0.5 m s^{-1} ($-0.75, -0.25, 0.25$) for zonal wind. Figure from *Thompson and Wallace [2000]*.

Nigam [1990] who found barotropic and baroclinic modes of the zonal-mean zonal wind which vary coherently in the troposphere and stratosphere. This analysis was extended by *Baldwin et al.* [1994] who found significant correlations between stratospheric and tropospheric EOFs of daily NH geopotential height (patterns which would now be referred to as annular modes). However, they found that the strongest correlations occurred with the troposphere leading, and while suggesting that the stratosphere may exert some influence on the troposphere, they concluded that the direction of causality was mostly upwards.

These studies were followed by several others which looked at the co-variability of the stratospheric and tropospheric annular modes, and demonstrated links between the strength of the polar vortex and surface temperature and sea level pressure patterns [*Perlitz and Graf*, 1995; *Thompson and Wallace*, 1998; *Baldwin and Dunkerton*, 1999]. However, it was *Baldwin and Dunkerton* [2001] who first demonstrated that the stratosphere-troposphere link is particularly strong following extreme weakenings or strengthenings of the stratospheric polar vortex. Figure 2.7 shows a time series of the NAM during the winter of 1998–1999, which includes two such weak vortex events (in December and February), characterised by a negative stratospheric NAM (these events are highly correlated with SSWs). It is apparent that NAM signal appears to descend in the case of the latter event (but not the former) and consistent anomalies remain in the troposphere for approximately one month. This timescale is much longer than the usual timescales of tropospheric NAM variability [e.g., *Simpson et al.*, 2011] but is more representative of the time taken for the stratosphere polar vortex to recover following a SSW.

Most observational studies of stratosphere-troposphere coupling have focused on the NH because of the greater stratospheric variability there. However, *Thompson and Solomon* [2002] argued that a long-term strengthening of the SH stratospheric polar vortex resulting from ozone depletion may be causing trends in the tropospheric SAM through a dynamical link. This was supported by *Thompson et al.* [2005], who performed an analysis similar to *Baldwin and Dunkerton* [2001], finding long-lived tropospheric SAM anomalies following strengthenings

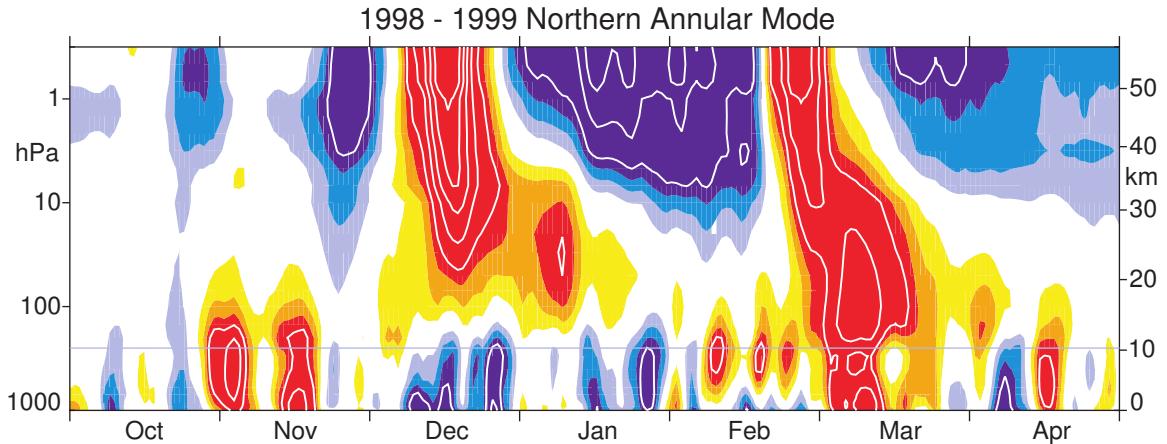

Figure 2.7: Time-height development of the northern annular mode during the winter of 1998–1999. The indices have daily resolution and are nondimensional. Blue corresponds to positive values (strong polar vortex), and red corresponds to negative values (weak polar vortex). The contour interval is 0.5, with values between –0.5 and 0.5 unshaded. The thin horizontal line indicates the approximate boundary between the troposphere and the stratosphere. Figure from *Baldwin and Dunkerton [2001]*.

and weakenings of the SH stratospheric polar vortex (although these have a much smaller magnitude to the NH equivalents). They also found a strong tropospheric SAM signal following the 2002 SH SSW.

More recent studies of tropospheric anomalies following stratospheric events have focused on more localised extreme weather events in addition to the annular modes. Several such studies have found associations between weakenings of the NH stratospheric polar vortex and an increased likelihood of extreme cold events over North America, northern Europe and eastern Asia [*Thompson et al., 2002; Koldstad et al., 2010; Tomassini et al., 2012*]. These extreme cold events are often linked with persistent ‘blocking’ weather patterns,¹¹ and a number of studies have investigated the association between stratospheric variability and blocking. Although *Taguchi* [2008] found no statistically significant change in blocking frequency during periods before or after SSWs, several studies have asserted an upwards link, with blocking events preceding a weakened polar vortex [*Quiroz, 1986; Andrews et al., 1987; O'Neill et al., 1994*]. More recent studies have further investigated whether blocking in particular locations precedes split or displaced vortex events,

¹¹These are characterised by a persistent anticyclonic anomaly that causes a reversal in the upper-tropospheric meridional gradient of a quantity such geopotential height [e.g., *Tibaldi and Molteni, 1990*].

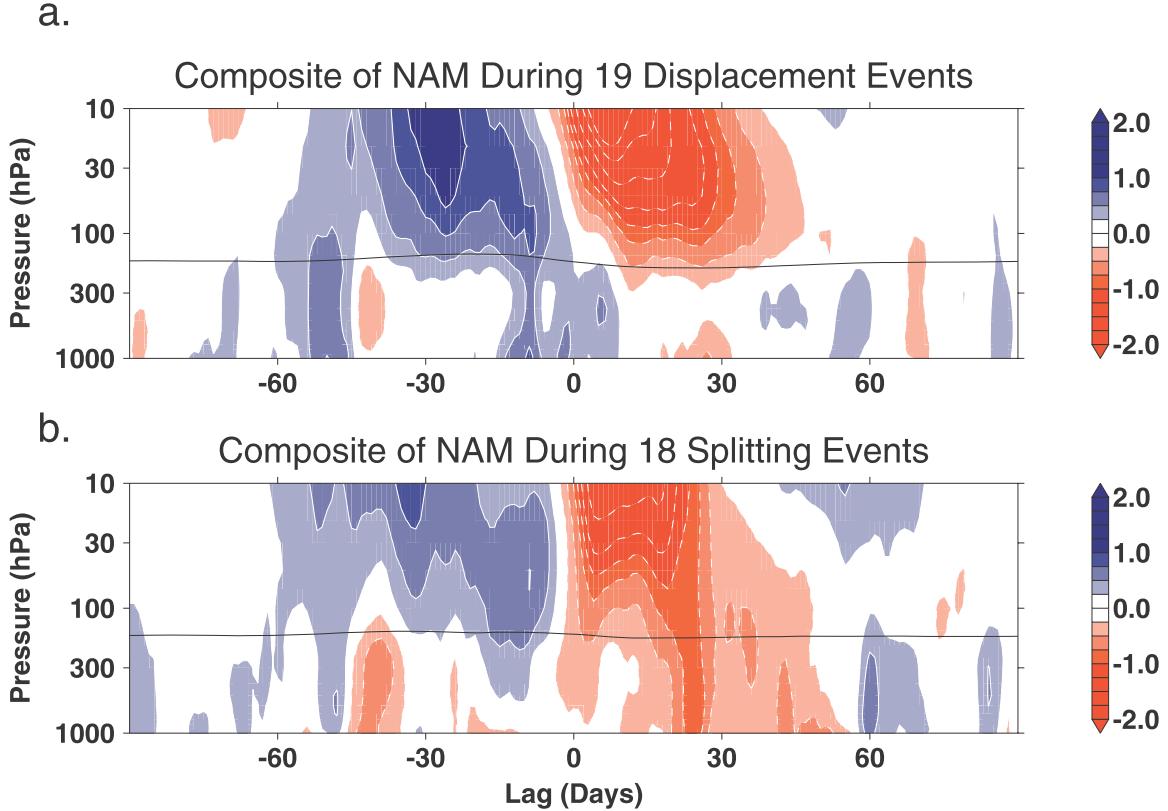

Figure 2.8: Composites of the time–height evolution of the NAM during (a) 19 vortex displacement events and (b) 18 splitting events. The horizontal line is a composite of the thermal tropopause level for the two types of event. Lag 0 shows the onset of an event as measured at 10 hPa. Contour intervals are 0.25 and the region between -0.25 and 0.25 is unshaded. Figure from [Mitchell et al. \[2013\]](#).

although these have reached conflicting conclusions [[Martius et al., 2009; Woollings et al., 2010; Castanheira and Barriopedro, 2010](#)]. A downwards link between stratospheric variability and the likelihood of blocking events was suggested by [Kodera and Chiba \[1995\]](#). [Woollings et al. \[2010\]](#) and [Davini et al. \[2014\]](#) have recently found more evidence for this link, including stratosphere-leading relationships between stratospheric variability and high-latitude blocking which may be associated with the stratospheric impact on the tropospheric NAM. Overall however, the nature of link between stratospheric variability and blocking remains uncertain and is a topic of active research.

It has been observed that some SSW events, while appearing to have similar magnitudes in the stratosphere, have very different signatures in the troposphere [e.g., [Baldwin and Dunkerton, 2001; Tomassini et al., 2012](#)] (See also the

2.4. STRATOSPHERE-TROPOSPHERE COUPLING

two events shown in Figure 2.7). This issue was addressed by *Nakagawa and Yamazaki [2006]* and *Mitchell et al. [2013]*, who compared tropospheric anomalies following SSWs dominated by wavenumber-1/wavenumber-2 activity and displaced/split vortex events respectively (these two classifications are related but not identical: e.g., *Waugh [1997]*, Section 3.1). These studies found stronger stratospheric anomalies following wavenumber-2/split vortex SSWs than following wavenumber-1/displaced vortex SSWs.¹² This result is illustrated in Figure 2.8, which shows composites of the NAM following the split and displaced vortex events identified by *Mitchell et al. [2013]*. It can be seen that tropospheric anomalies are stronger following split vortex events and persist for up to two months, while the NAM signal following displaced vortex events appears not to descend below the tropopause even though its stratospheric magnitude is greater. *Mitchell et al. [2013]* went on to link these different NAM signals to an increase in high-latitude blocking following split vortex events, and a weaker blocking signal following displaced vortex events. On the other hand *Charlton and Polvani [2007a]*, using a different classification method, found little difference in the tropospheric signals following split and displaced vortex events. This discrepancy between these studies highlights the importance of the classification method of split and displaced vortex events (or of tropospheric variability); an issue which is addressed in Chapter 3.

It is not only mid-winter stratospheric variability which has been suggested to influence tropospheric weather. *Hardiman et al. [2011]* found differences in NH springtime sea-level pressure anomalies following two types of stratospheric final warming; more radiatively driven final warmings where the transition to easterlies happens first in the upper stratosphere and descends with time, and more dynamically driven final warmings where the transition to easterlies happens first in the midstratosphere.

¹²Using the method developed in Chapter 3, of the two weak vortex events illustrated in Figure 2.7, the first is identified as a displaced vortex event and the second as a split vortex event. Their different tropospheric NAM may therefore be expected, although no firm conclusions should be reached from the study just two events.

A significant limitation of the above observational studies, which employ composite or correlation analysis, is that they cannot in themselves demonstrate *causation*. For example, there may be the possibility that a third factor (such as sea-surface temperatures) affects both the troposphere and stratosphere separately. To address this, a number of modelling studies have been carried out which measure the tropospheric response to some imposed stratospheric perturbation. These are described in the next section.

2.4.2 Modelling evidence

Modelling investigations into a possible stratospheric influence on the troposphere predate the observational evidence described above. In a general circulation model (GCM) study, *Boville* [1984] showed that changes to upper tropospheric and lower stratospheric zonal mean zonal winds have a significant effect on mid-troposphere wave fields, although the wind changes imposed in his model were larger than those in reality. Using more realistic wind variations, *Jacqmin and Lindzen* [1985] found the troposphere to be largely insensitive to changes in the state of the stratosphere. However, several more recent studies using models with a more realistic representation of stratospheric dynamics, have found a consistent tropospheric response to an imposed stratospheric torque [e.g., *Polvani and Kushner*, 2002; *Norton*, 2003; *Taguchi*, 2003]. This tropospheric response is found to resemble the negative phase of the NAO or NAM following a weakening of the vortex, and as such is consistent with the observational results discussed in the previous section.

Figure 2.9 shows the results from another such study by *Jung and Barkmeijer* [2006], who imposed a weakening of the stratospheric polar vortex using an adjoint method. Differences of zonal-mean zonal wind at four time periods following the imposition of this forcing are shown for the composite of 60 forecasts. It can be seen that anomalies are initially confined to the troposphere but descend to the troposphere after approximately 20 days. *Jung and Barkmeijer* [2006] also found surface anomalies associated with this forcing to resemble the negative phase of the NAO, though with the southern node shifted slightly eastwards.

2.4. STRATOSPHERE-TROPOSPHERE COUPLING

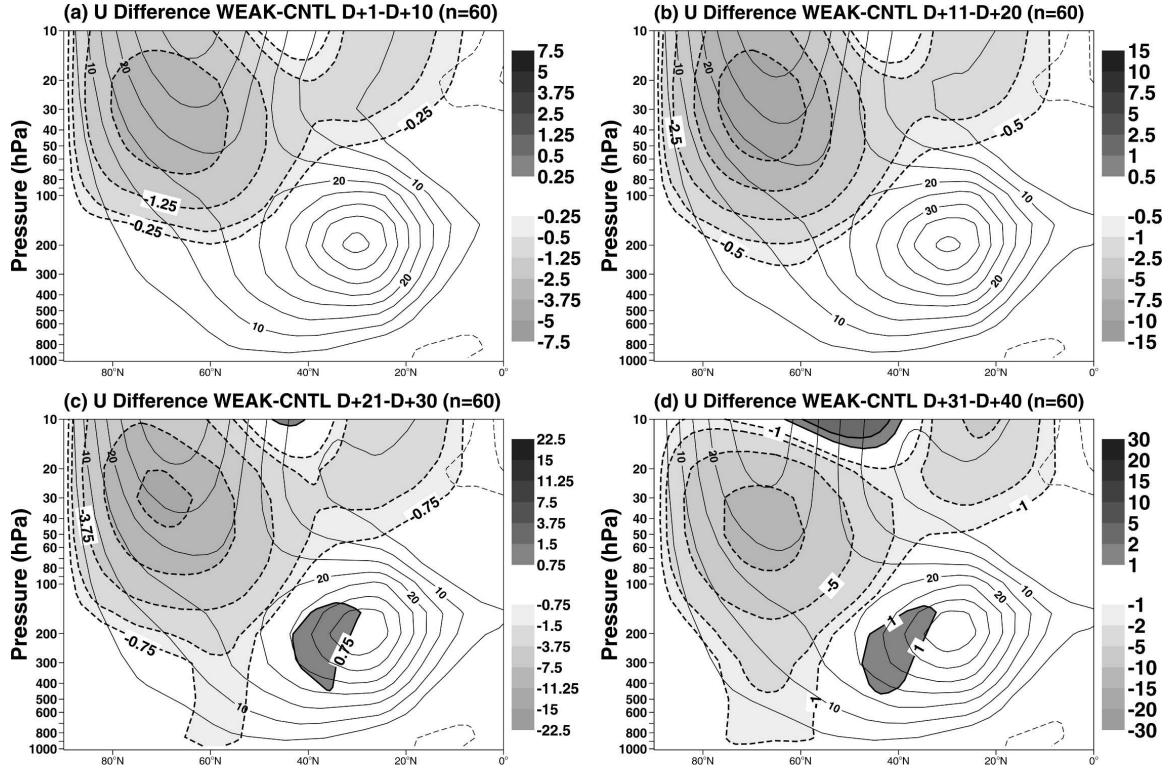

Figure 2.9: Difference of average zonal-mean zonal winds (shading in m s^{-1}) between the weak polar vortex (WEAK) and the control experiment (CNTL) for 10-day averages: (a) D +1 to D +10, (b) D +11 to D +20, (c) D +21 to D +30, and (d) D + 31 to D +40. Shown is the average over 60 different cases (40-day integrations). Notice that the contour interval for the differences changes linearly with the forecast range. Also shown are zonal-mean zonal winds from the control integration (contour interval is 5 m s^{-1}). Figure from [Jung and Barkmeijer \[2006\]](#).

Interestingly, they found an almost opposite surface response when a strengthening of the stratospheric polar vortex was imposed. This indicates that the surface response may be linear, potentially providing some information about the mechanism responsible for the response, as discussed in the next section.

This tropospheric response to an imposed torque was shown to also operate on long time scales by [Scaife et al. \[2005a\]](#). They found that when a long-term acceleration of the stratospheric polar vortex was imposed from the 1960s–1990s, in line with observations, their model more faithfully reproduced the long-term trend towards a more positive phase of the NAO over this time. It is however, important to note that this does not necessarily imply that stratospheric changes were driving the trend in reality.

In contrast to the studies above, which have calculated the tropospheric response to an imposed stratospheric forcing, *Simpson et al.* [2011] removed the stratospheric influence by damping the polar stratosphere to a climatological seasonal cycle. In doing so, they found that the effect of the stratosphere is to lengthen SAM timescales¹³ during the austral late spring/early summer, and to lengthen NAM timescales during the boreal winter-spring.

A criticism of studies with an imposed damping or torque is that they may not be simulating a balanced, realistic, or physical state (for instance, the imposed torque may not conserve angular momentum). As such, several studies have taken place using free-running GCMs. *Plumb and Semeniuk* [2003] found using a simple free-running stratosphere-only model that descending annular mode-like signals of the kind shown in Figure 2.7 can be simulated only by changing the forcing at the lower boundary. They therefore conclude that observations of this kind do not necessarily indicate a downwards influence from the stratosphere. However, *Gerber et al.* [2008] undertook a similar study, comparing relatively simple GCM simulations with varying representations of the stratosphere. They altered the strength and variability of the stratospheric polar vortex independently of the troposphere by varying the stratospheric lapse rate, finding that simulations with a more variable polar vortex also had longer timescales of the tropospheric NAM (a result similar to that of *Simpson et al.* [2011], although using a free-running model). This lengthened timescale, in turn, was related to the long-lived tropospheric anomalies following SSWs. Using the same model, *Gerber et al.* [2009] performed a series of ensemble forecasts of model-simulated SSW events. They compared events in which the initial tropospheric NAM was negative and positive, finding a negative NAM to be much more likely following the SSW event in both cases. Hence, they conclude that the stratosphere does indeed exert a significant downwards influence on the troposphere in their model.

A further class of model investigation has been to compare models with a well-resolved stratosphere with models with a coarser stratospheric resolution;

¹³The SAM/NAM timescale is defined as the lag (in days) for its autocorrelation to fall by $1/e$.

known as ‘high-top’ and ‘low-top’ models respectively [*Huebener et al.*, 2007; *Sigmond et al.*, 2008; *Cagnazzo and Manzini*, 2009; *Sassi et al.*, 2010; *Scaife et al.*, 2011a; *Charlton-Perez et al.*, 2013] (discussed in greater detail in Section 4.1). These have all indicated a more realistic representation of tropospheric variability and long-term trends is achieved with improved vertical resolution. Additionally, in a case study of the cold European winter 2005–2006, *Scaife et al.* [2008] found increased blocking activity in a model with greater stratospheric resolution. On the other hand, in a multi-model comparison of blocking, *Anstey et al.* [2013] found a stronger relationship between blocking frequency and upper-troposphere/lower-stratosphere vertical resolution than with model lid height. Overall, large biases remain in models’ representation of blocking. A difficulty of these studies is that there are often several differences between high- and low-top models besides their vertical resolution (such as their parametrisation schemes), so it is difficult to pin down any differences between the simulations to a stratospheric influence alone. *Hardiman et al.* [2012a] attempted to address this issue by comparing model simulations which differ only in their vertical resolution above 15 km. They found the climatology and trends of surface temperature to be largely insensitive to the increased vertical resolution, although stronger surface anomalies following SSWs and a more realistic trend in the NAO were found in the high-top model.

Several studies have investigated the influence of the stratosphere on the skill of medium-range forecasts (also discussed in Section 5.1). These have demonstrated improvements in the medium-range predictive skill of high-top relative to low-top models [*Marshall and Scaife*, 2010; *Roff et al.*, 2011], and enhanced predictability when forecasts are initialised at the time of anomalously negative stratospheric NAM or SSWs [*Kuroda*, 2008; *Mukougawa et al.*, 2009; *Sigmond et al.*, 2013]. These studies therefore further indicate a downwards influence of stratospheric variability on the troposphere.

2.4.3 Mechanisms

The results described in the previous two sections provide strong evidence that the stratosphere does indeed exert a significant influence on tropospheric weather

and climate. Even so, many uncertainties about the exact nature of the influence remain; observational studies are always open to the criticism that they do not demonstrate causality, and modelling studies that they contain large model biases or are simulating an unrealistic scenario. A coherent picture of stratosphere-troposphere coupling also requires a physical understanding of the mechanism by which this takes place. Several such mechanisms have been proposed, and are briefly described below:

- **Radiative effects:** It is well known that stratospheric (particularly lower-stratospheric) temperature increases following SSWs lead to increasing downwelling longwave radiation entering the troposphere. *Ramanathan* [1977] argued that this warming could reduce the available potential energy accessible to tropospheric eddy activity. Similarly, the stratospheric cooling associated with ozone depletion leads to a reduction in downwelling longwave radiation entering the troposphere [*Forster and Shine*, 1997]. *Grise et al.* [2009] used a radiative transfer model to assess the impact of these radiation changes, finding a significant impact on surface polar temperatures, although they did not assess the circulation response. Indeed, relatively few studies have assessed the impact of radiative processes in stratosphere-troposphere coupling in the light of more recent observations. Despite this, it is unlikely that radiative effects play a large role in the observed stratosphere-troposphere coupling since relatively realistic coupling can be simulated in a model lacking interactive ozone or a detailed radiation scheme.
- **Baroclinic instability:** The growth rate of baroclinic eddies is related to the vertical shear in zonal wind across the troposphere [*Eady*, 1949]. Some studies have suggested that lower stratospheric zonal wind anomalies which penetrate into the upper troposphere affect this vertical wind shear, and so the growth of baroclinic eddies [*Wittman et al.*, 2007; *Chen and Zurita-Gotor*, 2008]. Hence, we may expect reduced tropospheric eddy activity at mid-high latitudes following SSWs, due to weaker lower stratosphere/upper troposphere zonal winds. *Scaife et al.* [2011a] also used this relationship

to demonstrate that an increase in European winter storminess and equatorward shift in the North Atlantic storm track projected under climate change are consistent with a strengthening and equatorward shift of the stratospheric polar vortex. It is less clear what effect whether the change in baroclinic eddy activity is sufficient to lead to the annular mode signals of the kind shown in Figure 2.7, although tropospheric eddies have been demonstrated to be important in driving annular mode variability [*Limpasuvan and Hartmann, 1999*].

- **Downward control:** Under steady-state or time-mean conditions, the ‘downward control’ principle of *Haynes et al. [1991]* allows the streamfunction, ψ , of the TEM residual circulation is given by

$$\psi(\phi, z) = \int_z^\infty \left(\frac{\rho_0 a \bar{F} \cos^2 \phi}{\partial \bar{m} / \partial \phi} \right)_{\phi=\phi(z')} dz', \quad (2.13)$$

where \bar{F} is the total wave driving term from Equation 2.10, and $\bar{m} = a \cos \phi (\bar{u} + a \Omega \cos \phi)$ is the angular momentum per unit mass. Strictly, the integration is along a line of constant angular momentum, but this is approximated as vertical (an approximation which breaks down near the equator). Hence, it can be seen that under these conditions the residual circulation at a given altitude depends only on the wave drag above that altitude.

This relation therefore shows that circulation induced by stratospheric wave drag extends to the Earth’s surface, although it should be noted above assumptions (particularly steady-state) do not strictly hold in the real atmosphere. *Thompson et al. [2006]* suggested that this induced residual circulation (or ‘balanced response’) is sufficient to explain the observed stratosphere-troposphere coupling. Others, however, have argued that the observed annular mode-like tropospheric response cannot be generated in the zonal-mean framework of downward control, necessitating feedbacks involving tropospheric eddies [*Kushner and Polvani, 2004; Song and Robinson, 2004*].

- **Planetary wave reflection:** The critical surface formed in the stratosphere during SSW events acts to reflect upwards-propagating planetary waves, as

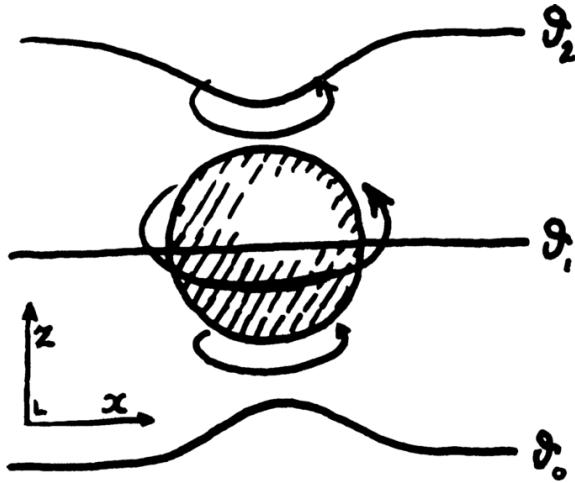

Figure 2.10: Schematic of the bending of isentropic surfaces (labelled θ_0 , θ_1 , and θ_2) toward a positive potential vorticity anomaly. The arrows represent winds associated with the potential vorticity anomaly, becoming weaker away from the anomaly. Figure from *Ambeam and Hoskins [2002]*.

described in Section 2.1.2.1. *Perlitz and Harnick [2003]* argued that these reflected planetary waves re-enter the troposphere and affect the tropospheric wave structures, leading to the observed tropospheric response. *Shaw et al. [2010]* have further suggested that strong two-way coupling exists in the presence of both a vertical reflecting surface and a strong meridional PV gradient, which act to create a ‘wave guide’.

- **Local adjustment to PV anomalies:** Anomalies of PV act to bend isentropic surfaces [*Hoskins et al., 1985*], as shown in the schematic from *Ambeam and Hoskins [2002]* (Figure 2.10). At high latitudes, the tropopause lies approximately on a potential vorticity surface, also the potential temperature of the tropopause will be conserved for adiabatic changes (Section 2.1.2.1). Hence, the tropopause will also bend for a stratospheric potential vorticity anomaly; moving upwards for a positive anomaly, and downwards for a negative anomaly. This deformation of the tropopause induced by a stratospheric PV anomaly will lead to hydrostatic and geostrophic adjustment of the tropospheric column below. [*Hartley et al., 1998; Black, 2002; Ambeam and Hoskins, 2002*]

CHAPTER 3

A geometrical description of vortex variability

Much of the work contained in this chapter is based upon *Seviour et al.* [2013], published in *Geophysical Research Letters*, although the analysis presented here has been significantly extended.

3.1 Introduction

A quantitative description of stratospheric polar vortex variability is desirable for a number of reasons; it allows for the comparison of different studies, observational data sets, and model simulations, as well as permitting robust definitions of extreme events. Traditional methods to quantify vortex variability have been based on zonal-mean diagnostics, such as the zonal-mean zonal wind [e.g., *Andrews et al.*, 1987]. This was motivated both by the simplicity of these diagnostics and the physical reasoning that the strength of the zonal flow controls the propagation of planetary waves [*Charney and Drazin*, 1961, Section 2.1.2]. *McInturff* [1978] provided the first quantitative definition of SSWs¹ (referred to in that text as “major stratospheric warmings”) using zonal mean quantities as below.

“A stratospheric warming can be said to be major if at 10 mb or below the latitudinal mean temperature increases poleward from 60

¹In the literature, this is often called “the WMO definition”.

degrees latitude and an associated circulation reversal is observed (i.e., mean westerly winds poleward of 60° latitude are succeeded by mean easterlies in the same area)."

A number of variations of this definition have since appeared in the literature. Most commonly, the temperature gradient criterion has been neglected and/or zonal wind reversals at a particular latitude (usually 60°N) used instead of the stricter criterion of a reversal everywhere poleward of 60°N [e.g., *Labitzke and Naujokat, 2000; Christiansen, 2001; Reichler et al., 2012*].

Although the reversal of zonal-mean zonal wind is physically relevant for the propagation of planetary waves, the choice of 60°N and 10 hPa in the definition of SSWs is less physically significant. Indeed, different numbers of SSWs are identified if these locations are varied. *Butler et al. [2014]* found that a greater number of events are identified if the threshold is located either equatorward or poleward of 60°N . Some studies have aimed to avoid this sensitivity to spatial location by quantifying vortex variability through empirical orthogonal function (EOF) analysis, using fields over a larger area. This includes the Northern Annular Mode (NAM) (calculated either from the three-dimensional geopotential height field [*Baldwin and Dunkerton, 2001*] or zonal-mean geopotential height [*Baldwin and Thompson, 2009*]), EOFs of zonal wind [*Limpasuvan et al., 2004*], and vertical profiles of polar cap-averaged temperature [*Kuroda, 2004*]. SSW events are then defined by a threshold in the principal component of the relevant EOF.

As it has become increasingly recognised that SSWs generally occur as either split or displaced vortex events, studies have aimed to objectively distinguish these two types of event. Commonly this has been achieved through Fourier decomposition of the zonal wave structure. For instance, *Nakagawa and Yamazaki [2006]* defined SSWs through a polar temperature criterion and then split these events into two groups depending on whether the 150 hPa Eliassen-Palm (EP) flux prior to the events was dominated by zonal wavenumber one or two. *Charlton and Polvani [2007b]* (hereafter CP07) introduced a new classification method, which does not rely on Fourier decomposition; first they identified events using the traditional wind reversal at 60°N , 10 hPa criterion, then they calculated the

3.1. INTRODUCTION

circulation around the two largest contours of relative vorticity on the vortex edge. If these two contours have a circulation ratio of 2:1 or lower the event is classified as a split, and all other events are automatically classed as displacements.

Both Fourier decomposition of the zonal wave structure and the method of *Charlton and Polvani* [2007b] rely on an Eulerian framework, with fields analysed at a fixed spatial location. *Waugh* [1997] first applied two-dimensional moment diagnostics (otherwise known as elliptical diagnostics) to the stratospheric polar vortex to provide an alternative semi-Lagrangian (or vortex-oriented) framework. These diagnostics are calculated by fitting an ellipse to a contour and then determining its properties such as the centre, orientation, aspect ratio, and area (a further diagnostic, excess kurtosis—a measure of the ‘peakedness’ of the distribution—was introduced by *Matthewman et al.* [2009]). This allows the movement and elongation of the vortex to be quantified. *Waugh* [1997] also compared these diagnostics to the traditional Fourier decomposition. He showed that wave 1 and 2 amplitudes relate most strongly to the displacement and elongation of the vortex respectively, however, these relationships were not found to be strong, with correlations of daily values less than 0.5. These weak relationships were attributed to the fact that planetary wave propagation can be affected by changes in the meridional PV gradient, even if the vortex shape and location are fixed. Furthermore, the wave 1 amplitude depends to some extent on the elongation of the vortex as well as the location of the centre (and similarly for the wave 2 amplitude). He concluded that it is difficult to extract quantitative information about the shape and location of the vortex based on wave amplitudes alone, highlighting the advantages of the moment diagnostics.

Hannachi et al. [2010] then applied a hierarchical clustering algorithm to daily values of the area, centroid latitude, and aspect ratio diagnostics and found that the vortex falls preferably into three clusters corresponding to undisturbed, split, and displaced states. These groupings were used by *Mitchell et al.* [2013] (hereafter M13) to identify split and displaced vortex events; if the vortex remained in the split or displaced cluster for at least five consecutive days it was classified as

the corresponding event. Significantly, as discussed in Section 2.4.1, M13 demonstrated that split vortex events penetrated deep into the troposphere and resulted in significant surface anomalies, while anomalies associated with displaced vortex events do not descend far below the tropopause. This is in agreement with *Nakagawa and Yamazaki* [2006] who found tropospheric anomalies to be larger following SSWs with dominant wave 2 amplitude, however, it contrasts with *Charlton and Polvani* [2007b], who found little difference in the tropospheric impact of split and displaced vortex events. This highlights the potential importance of the method of classification of split and displaced vortex events in any study.

In this chapter we wish to develop a method for the classification of split and displaced vortex events with the following properties:

1. Based on vortex moment diagnostics.
2. Can be easily applied to a range of data sets, including climate model simulations.
3. Computationally inexpensive.

The motivation for the use of moment diagnostics includes their advantages in quantifying the shape and location of the vortex, as noted above. This, in turn, is desirable because the location of the vortex near the tropopause may be important for understanding the regional tropospheric effect of stratospheric anomalies [e.g., *Amбаум and Hoskins*, 2002, Section 2.4.3]. Previous calculations of vortex moment diagnostics have been based on the distributions of quasi-conservative tracers such as PV on isentropic surfaces [*Mitchell et al.*, 2011a] or long-lived tracer (e.g., N₂O) concentrations [*Waugh*, 1997]. These quantities have strong meridional gradients allowing for clear determination of the vortex edge [*Nash et al.*, 1996]. Unfortunately, many climate models do not output PV or tracer concentrations, and these are often computationally expensive or impractical to calculate. As such, we wish to develop a method which uses geopotential height, a variable which is output by all contemporary climate models. This effort will also allow

us to test the robustness of the result of M13 regarding the different surface impacts of split and displaced vortex events using a semi-independent classification method and extended data set.

The remainder of this chapter is structured as follows. The next section introduces the necessary theoretical background for the calculation of moment diagnostics. Section 3.3 describes the methods used for the classification of split and displaced vortex events, and compares these events with those determined by M13 and CP07. Section 3.4 contrasts the surface impacts of split and displaced vortex events calculated using the new method and discusses potential mechanisms behind any differences.

3.2 Vortex moment diagnostics

The moments, M_n , of a one-dimensional distribution can be classified by their order, n , and provide familiar parameters. These are the area under the distribution (0th order), mean (1st order), variance (2nd order), skewness (3rd order), and kurtosis (4th order), given by

$$M_n = \int_S x^n f(x) dx, \quad (3.1)$$

where S represents the extent of the distribution, $f(x)$, to be integrated over. The extension of this for a two-dimensional distribution is straightforwardly

$$M_{nm} = \iint_S x^n y^m f(x, y) dx dy, \quad (3.2)$$

where the order of the moment is now defined as $m + n$, meaning it is possible to have different diagnostics with the same order (e.g., M_{01} , M_{10}). Although these diagnostics can be further extended to three dimensions, this has been demonstrated to be highly computationally expensive [Li and Ma, 1994], and would require assumptions about the lower and upper bounds of the vortex region. We therefore calculate two-dimensional moment diagnostics for the stratospheric polar vortex on quasi-horizontal surfaces. We use two variables; geopotential height ($f(x, y) = Z(x, y)$) on the 10 hPa pressure level, and potential vorticity

$(f(x, y) = q(x, y))$ on the 850 K potential temperature (isentropic) surface, which lies close to 10 hPa. Following *Waugh* [1997], the calculation of moment diagnostics is simplified by transforming the spherical data $q(\phi, \lambda)$ and $Z(\phi, \lambda)$, where ϕ is latitude and λ longitude, to Cartesian coordinates using the polar stereographic projection

$$x = \frac{\cos \lambda \cos \phi}{1 \pm \sin \phi}, \quad y = \frac{\pm \sin \lambda \cos \phi}{1 \pm \sin \phi}, \quad (3.3)$$

where the positive sign is used in the Northern Hemisphere and negative in the Southern Hemisphere.

In order to calculate moment diagnostics for the stratospheric polar vortex we must first isolate the vortex region by defining the vortex edge. Different methods have previously been used for this calculation; *Waugh and Randel* [1999] used the mean PV at the maximum of the mean meridional PV gradient, while *Matthewman et al.* [2009] defined the vortex edge on a daily basis, using the average value of PV poleward of 45°N nine days before the onset of a SSW (their SSWs were defined by zonal-mean zonal wind reversal, as in CP07). A more complex method due to *Nash et al.* [1996], starts by transforming PV to ‘equivalent latitude’ [*Butchart and Remsberg*, 1986] coordinates, before defining the vortex edge as the position of the largest gradient in a plot of PV against equivalent latitude. This method was applied in *Mitchell et al.* [2011a] to calculate the vortex edge.

None of the three methods outlined above are found to be appropriate for the present study. We wish to directly compare the PV and geopotential height-derived moments, but the methods of *Waugh and Randel* [1999] and *Nash et al.* [1996] rely on meridional gradients in PV and so may not be transferable to geopotential height. Furthermore, the method of *Matthewman et al.* [2009] is impractical because we wish to define the events from the moment diagnostics, so will not know their dates before calculation. Instead, we pick a simple definition; PV (q_b) or geopotential height (Z_b) on the vortex edge is defined as the value of the December-March (DJFM) mean at 60°N for the Northern Hemisphere and the June-September (JJAS) mean at 60°S for the Southern Hemisphere. This is seen to lie close to contours defined by the above methods, and results are insensitive to small changes in the latitude chosen.

3.2. VORTEX MOMENT DIAGNOSTICS

Having defined the vortex edge, we extend the method [Matthewman et al. \[2009\]](#) to isolate the vortex region by introducing a transformed PV field, \hat{q} , given by

$$\hat{q}(x, y) = \begin{cases} q(x, y) - q_b & \text{if } q(x, y) > q_b, \\ 0 & \text{if } q(x, y) \leq q_b, \end{cases} \quad (3.4)$$

and similarly for geopotential height

$$\hat{Z}(x, y) = \begin{cases} Z(x, y) - Z_b & \text{if } Z(x, y) < Z_b, \\ 0 & \text{if } Z(x, y) \geq Z_b. \end{cases} \quad (3.5)$$

By substituting $f(x, y) = \hat{q}(x, y)$ or $f(x, y) = \hat{Z}(x, y)$ in equation 3.2 it is then possible to calculate the moment diagnostics. The zeroth order moment diagnostic, M_{00} can be used to define the ‘equivalent area’, A_{eq} [[Matthewman et al., 2009](#)], as

$$A_{\text{eq}} = \frac{M_{00}}{q_b} \quad \text{or} \quad A_{\text{eq}} = \frac{M_{00}}{Z_b}, \quad (3.6)$$

depending on whether PV or geopotential height based diagnostics are calculated. Because $M_{00} \approx Aq$, where A is the vortex area, the equivalent area can be considered a measure of both vortex strength and area. The first order moment diagnostic can be used to calculate the vortex centroid,

$$(\bar{x}, \bar{y}) = \left(\frac{M_{10}}{M_{00}}, \frac{M_{01}}{M_{00}} \right). \quad (3.7)$$

In order for higher order moment diagnostics to be useful, the moment equation (3.2), must be transformed to the *centralised moment* form [[Hall, 2005](#)]. This calculates moments relative to the vortex centroid, and is given by

$$J_{mn} = \iint_S f(x, y)(x - \bar{x})^n(y - \bar{y})^m dx dy. \quad (3.8)$$

Two useful parameters can be derived from the second-order centralised moment diagnostics, the vortex orientation, ψ (defined as the angle between the major axis of the ellipse and the x -axis) and the aspect ratio, r (defined as the ratio of the lengths of the major to minor axes), given by

$$\psi = \frac{1}{2} \tan^{-1} \left(\frac{2J_{11}}{J_{20} - J_{02}} \right), \quad (3.9)$$

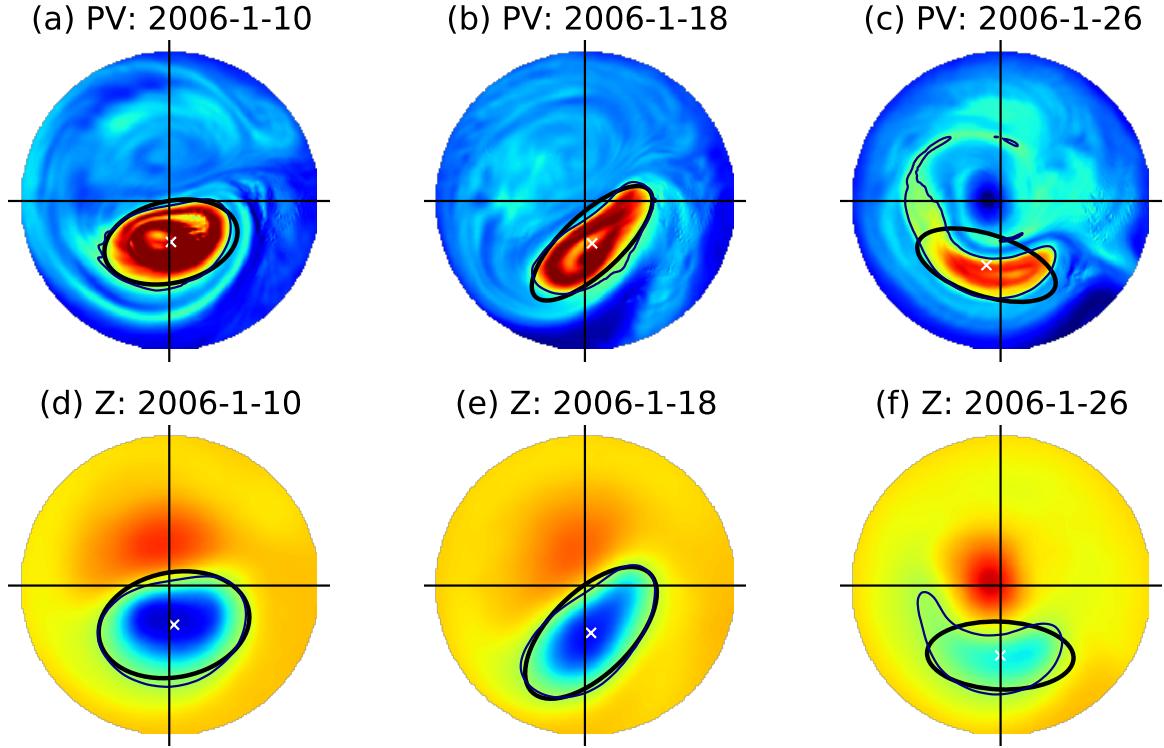

Figure 3.1: PV on the 850 K θ surface (a,b,c) and geopotential height at 10 hPa (d,e,f) 8 days before (a,d), at onset (b,e), and 8 days following the onset (c,f) of a displaced vortex event. Contours of q_b and Z_b are shown in thin black lines, the equivalent ellipse in a thick dark line, and its centroid with a white cross. Data are transformed to Cartesian coordinates with a polar stereographic projection.

$$r = \left| \frac{(J_{20} + J_{02}) + \sqrt{4J_{11}^2 + (J_{20} - J_{02})^2}}{(J_{20} + J_{02}) - \sqrt{4J_{11}^2 + (J_{20} - J_{02})^2}} \right|^{1/2}. \quad (3.10)$$

Using the area, centroid, orientation, and aspect ratio, the *equivalent ellipse* can be uniquely defined. Figure 3.1 shows the equivalent ellipse calculated from both PV and geopotential height fields over a 16-day period centred on a displaced vortex event (classified using the method in Section 3.3). It can be seen that the equivalent ellipse provides a qualitatively good fit to the vortex, although this is less good in Figures 3.1(c,f) when the vortex becomes less elliptical and filamentation occurs. Greater fine-scale structure and filamentation is visible in the PV field due to its quasi-conservative properties, however reasonable agreement can be seen between the PV and geopotential height ellipses.

Equivalent ellipses for an example of a split vortex event are shown in Figure

3.3. DATA AND METHODS

3.2. It can be seen that after the vortex has separated the equivalent ellipse becomes less physically significant, as it spans the two vortices. *Matthewman et al.* [2009] introduced the 4th order moment diagnostic, “excess kurtosis”, in order to identify splits of the polar vortex; it is given by

$$\kappa_4 = M_{00} \frac{J_{40} + 2J_{22} + J_{04}}{(J_{20} + J_{02})^2} - \frac{2}{3} \left[\frac{3r^4 + 2r^2 + 3}{(r^2 + 1)^2} \right]. \quad (3.11)$$

This has the property of being negative for a vortex with a “pinched” shape, zero for a perfectly elliptical vortex, and positive for a vortex with a strong central core. When negative kurtosis was detected *Matthewman et al.* [2009] split the PV field into two regions along the minor axis of the equivalent ellipse and re-calculated moment diagnostics for the vortices in these regions separately.

In this study we do not make use of the excess kurtosis or calculate separate diagnostics for split vortices for two reasons. First, as a 4th order diagnostic it is a highly skewed variable, making its use in event classification problematic (this was also found by *Hannachi et al.* [2010]). Second, this procedure is more computationally expensive, requiring about three times the number of calculations during split vortex events. Hence, we calculate single moment diagnostics even when the vortex has split, but bear in mind that these may not represent the properties of any real vortex.

Code for the calculation of moment diagnostics using the method described in this section is available from <https://github.com/wseviour/vortex-moments>.

3.3 Data and methods

3.3.1 Reanalysis data

For the analysis in this chapter Northern Hemisphere winter daily-mean data for December-March (DJFM) are employed from the European Centre for Medium-Range Weather Forecasts (ECMWF) reanalyses. The ERA-40 data set [*Uppala et al.*, 2005] is used from 1958-1978 and ERA-Interim [*Dee et al.*, 2011] from 1979-2009. The combination of these two data sets is chosen in order to maximise the total number of years entering the analysis (ERA-40 runs only to 2002), as well as to

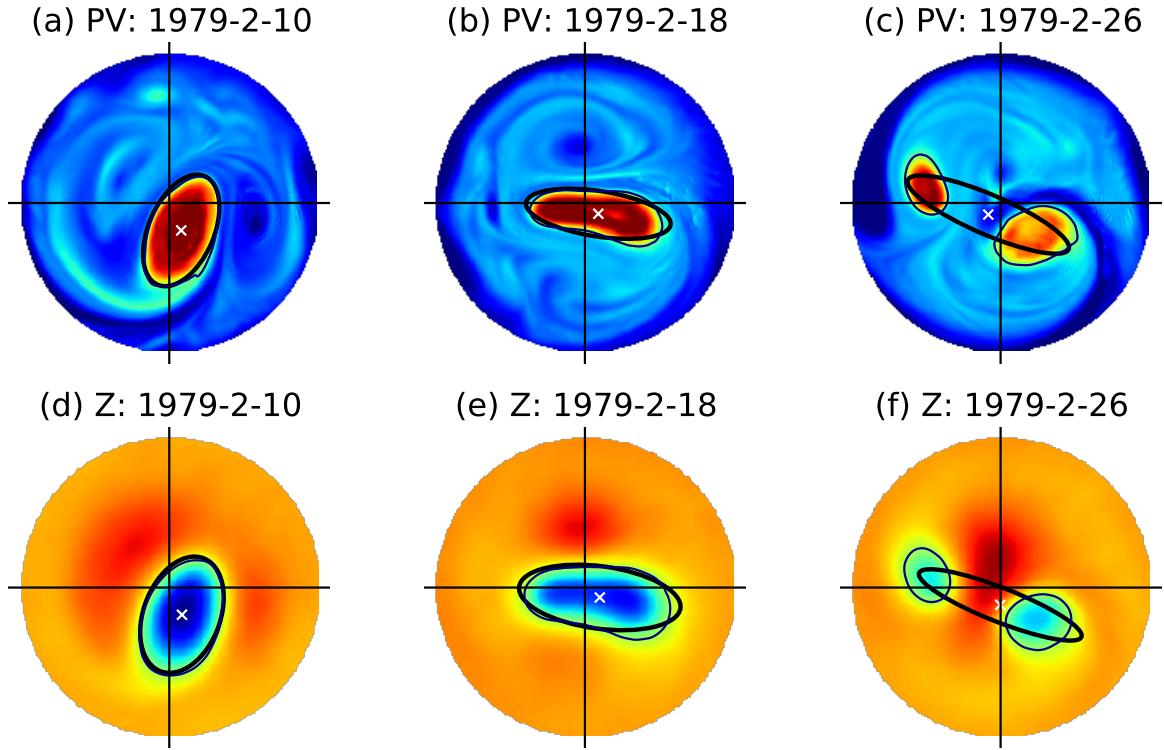

Figure 3.2: As Figure 3.1 but for a split vortex event.

compare results from the more recent ERA-Interim with previous studies using only ERA-40, such as *Charlton and Polvani [2007b]* and *Mitchell et al. [2013]*.

ERA-Interim is similar to ERA-40 but uses ECMWFs operational four-dimensional variational data assimilation system (4D-Var) as opposed to the 3D-Var system used in ERA-40. It also has higher horizontal and vertical resolution, improved humidity analysis, model physics, data quality control, bias handling and other improvements as noted in *Simmons [2007]*. The majority of observational data for the stratosphere entering both reanalyses is from radiosonde and satellite measurements. It is important to note that in the pre-satellite era (1958-1971) observations in the stratosphere were much more sparse, leading to greater errors in reanalyses during this time [*Uppala et al., 2005*].

A number of studies have evaluated the stratospheric circulation in ERA-40 and ERA-Interim against other observations or reanalyses. *Randel et al. [2004]* found ERA-40 to closely match measurements of the zonal stratospheric circulation derived from radiosonde, rocketsonde and lidar measurements. *Karpetchko*

3.3. DATA AND METHODS

et al. [2005] found that the representation of the polar vortices in ERA-40 agrees well with the NCEP/NCAR reanalysis, and CP07 demonstrated that this also holds for the occurrence of SSWs. *Seviour et al.* [2012] showed that the strength of the stratospheric meridional mean stratospheric circulation in ERA-Interim agrees well with previous reanalysis, but that the residual vertical velocity is more smoothly represented.

In order to perform a consistent analysis across the two data sets, ERA-Interim data is linearly interpolated to the lower resolution ERA-40 ($1.125^\circ \times 1.125^\circ$) Gaussian grid. PV is also interpolated from pressure levels to the 850 K isentropic surface (which lies close to 10 hPa), as this quantity has the property of being conserved under adiabatic flow. In the calculation of the vortex edge. Both in the calculation of the vortex edge (climatological mean q or Z at 60°N/S) and the moment diagnostics themselves, no clear jumps were seen between ERA-40 and ERA-Interim data sets. As such, the two are considered together with no bias corrections. For the remainder of this thesis, this combined ERA-40 and ERA-Interim data set is referred to as ‘ERA’.

3.3.2 Moment diagnostic calculation

In order to calculate the moment diagnostics, the values of PV and geopotential height on the vortex edge (q_b and Z_b) must first be determined. These are the $60^\circ\text{N DJFM}/60^\circ\text{S JJAS}$ mean values of PV at 850 K (q_{850}) and 10 hPa geopotential height (Z_{10}) respectively. They are found to be $q_b = 460$ PVU (1 PVU = $10^{-6}\text{Km}^2\text{kg}^{-1}\text{s}^{-1}$) and $Z_b = 30.2$ km for the Northern Hemisphere, and $q_b = 618$ PVU and $Z_b = 29.0$ km for the Southern Hemisphere. Using these values the moment diagnostics are calculated from ERA data for 1958–2009 using the method described in Section 3.2.

As discussed in Section 3.2 the excess kurtosis diagnostic is not used in the present analysis. In the interests of simplicity, only the aspect ratio and centroid latitude diagnostics are used to identify events, and the centroid longitude, orientation and equivalent area are not used. The aspect ratio and centroid latitude are the most intuitive diagnostics for this purpose, with a high aspect ratio and

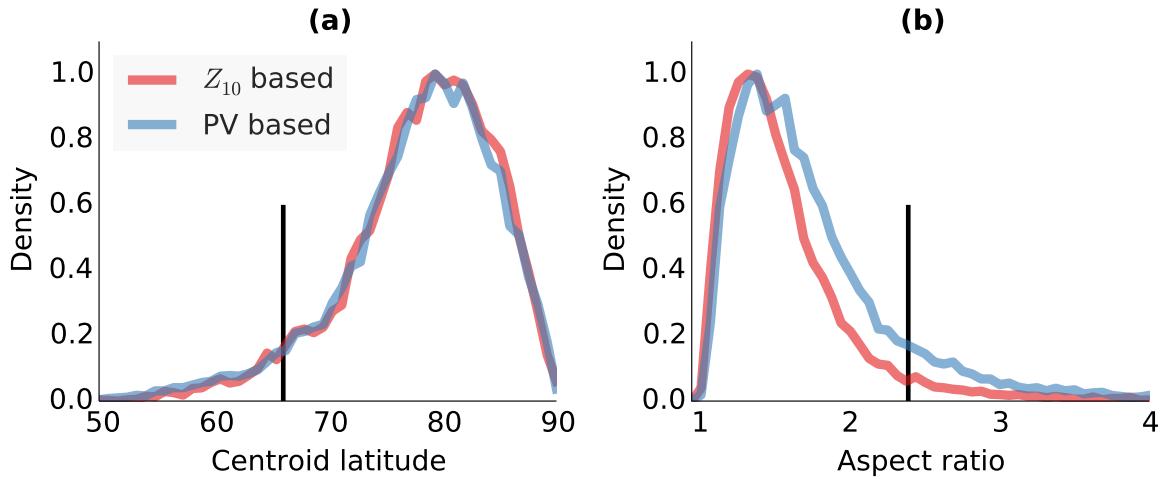

Figure 3.3: Distributions of the December-March centroid latitude (a) and aspect ratio (b), of the Northern Hemisphere stratospheric polar vortex over 1958-2009. Diagnostics are calculated from geopotential height at 10 hPa (Z_{10}) and potential vorticity at 850 K (PV). Thresholds of 66°N in centroid latitude and 2.4 in aspect ratio are used to define events, and are indicated by the black vertical lines.

poleward centroid latitude expected during split vortex events, and a low aspect ratio and equatorward centroid latitude expected during displaced vortex events.

Figure 3.3 shows the distributions of these two quantities calculated from q_{850} and Z_{10} for the Northern Hemisphere vortex. The centroid latitude distributions are almost identical, with a peak near 80°N which is in agreement with previous studies [Waugh and Randel, 1999; Mitchell *et al.*, 2011a]. The aspect ratio distributions have a similar shape, with a peak at about 1.3, but the PV based diagnostic has a larger tail. This is because the PV field contains more small-scale filamentary structures than geopotential height (e.g. Figures 3.1 and 3.2), making high aspect ratios more likely. As well as having similar distributions, the time series of the PV and geopotential height derived diagnostics (not shown) are significantly correlated, with correlation coefficients of 0.9 for daily centroid latitude and 0.6 for aspect ratio. Overall, these results suggest that geopotential height-derived moment diagnostics are appropriate for the identification of split and displaced vortex events.

Figure 3.4 shows the same distribution as Figure 3.3, but for the Southern Hemisphere vortex aspect ratio and centroid latitude. As in the case of the Northern Hemisphere, the geopotential height and PV-based distributions have very

3.3. DATA AND METHODS

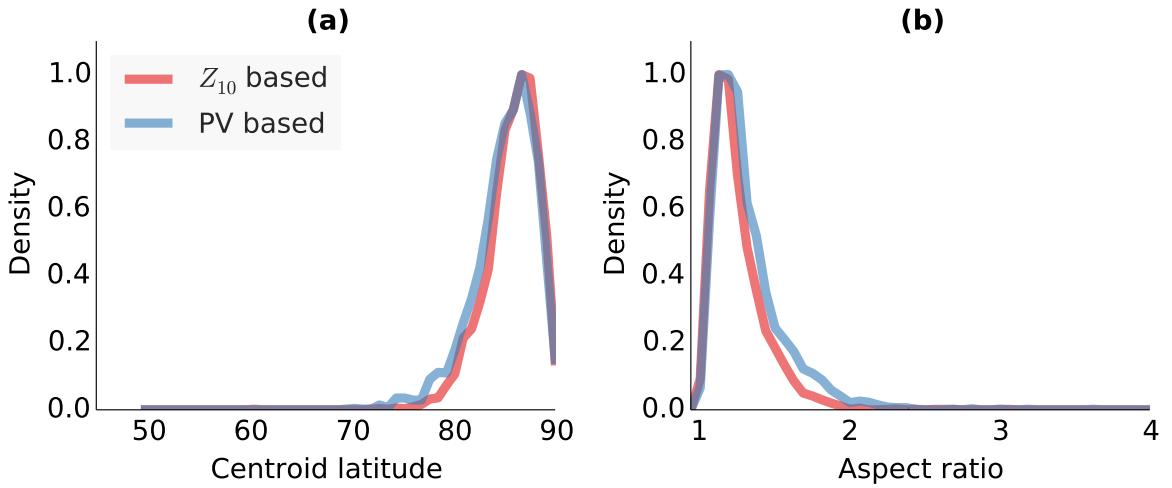

Figure 3.4: As Figure 3.3 but for moment diagnostics calculated for the Southern Hemisphere stratospheric polar vortex over June-September.

similar shapes, with the PV-based aspect ratio having a slightly larger tail. Comparing the Northern and Southern Hemisphere distributions it can be seen that there is much less variability in both aspect ratio and centroid latitude in the Southern Hemisphere. This is because of the reduced planetary wave propagation into the Southern Hemisphere stratosphere, in turn a result of lesser forcing from orography and land-sea temperature contrasts. The peak in the Southern Hemisphere centroid latitude is at about 86°S; the same as that found by *Waugh and Randel* [1999].

A result of this reduced Southern Hemisphere vortex variability is that only one SSW has been observed in the Southern Hemisphere (discussed further in Chapter 5). The rest of this chapter relates to the classification and impacts of split and displaced vortex events and so focuses only on the Northern Hemisphere. However, it should be noted that all the methods below can also be applied to the Southern Hemisphere.

3.3.3 Event identification

Previous attempts to identify SSW events have used a clustering method [*Coughlin and Gray*, 2009; *Hannachi et al.*, 2010]. These methods attempt to classify the vortex state for each day into a number of groups, which may be specified beforehand or determined by the clustering algorithm. Individual days within the same cluster

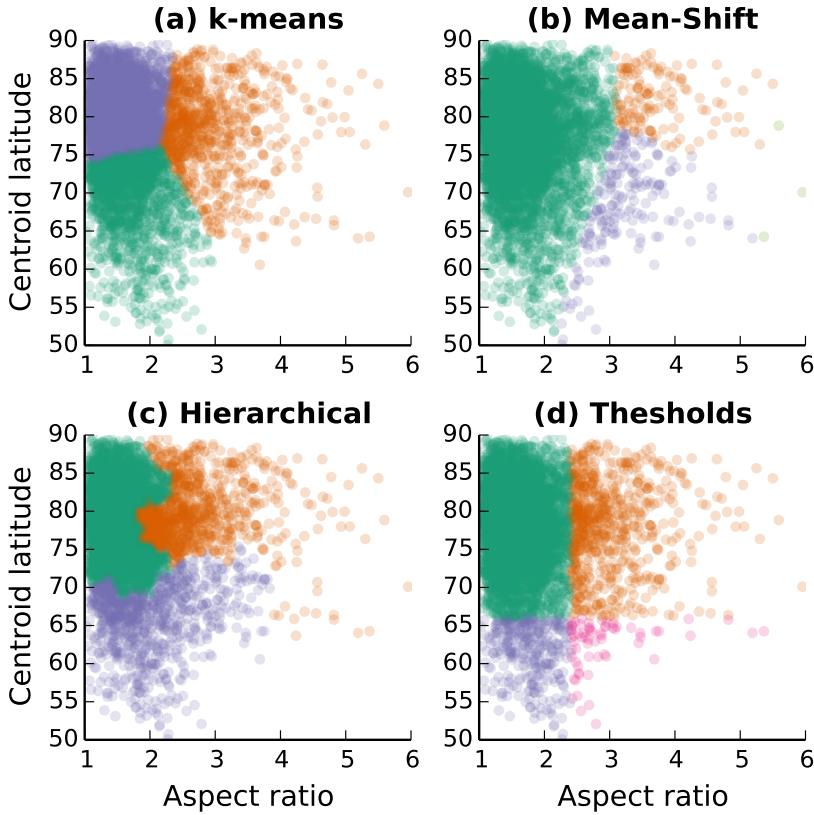

Figure 3.5: Three clustering algorithms and a threshold division applied to the moment diagnostics in centroid latitude-aspect ratio space. For the *k*-means and hierarchical algorithms three clusters were specified. The mean-shift algorithm determined the number of clusters to be 4.

should be physically similar, while those in different clusters distinct. More precisely, clustering aims to maximise the between-cluster variance while minimising the within-cluster variance. In the case of the stratospheric polar vortex, clusters may represent, for instance, stable, split, and displaced states. Events are then typically defined by the vortex persisting in a particular cluster for a number of days.

A large number of clustering algorithms exist, and some may be more appropriate than others for certain uses. Here, three different algorithms are applied to the moment diagnostics in centroid latitude-aspect ratio space, and their outcomes shown in Figure 3.5(a,b,c). Details of the three algorithms are given below:

- K-means** clustering requires the number of clusters, K , to be specified beforehand (in Figure 3.5, $K = 3$). The algorithm begins by randomly selecting K

3.3. DATA AND METHODS

data points to be the centroids of the initial clusters, all other data points are assigned to the cluster with the nearest centroid. Having assigned the initial cluster membership, the algorithm proceeds as follows:

1. Compute the centroids (the vector means), $\bar{\mathbf{x}}_k$ of each cluster.
2. Calculate the distance between the current data point, \mathbf{x}_i , and each of the K $\bar{\mathbf{x}}_k$ s. (Various distance measures can be used; in Figure 3.5(a), the Euclidean distance is used).
3. If \mathbf{x}_i is not in the group with the closest mean then reassign it to that group, otherwise repeat step 2 for \mathbf{x}_{i+1} .

This is repeated until a full cycle through each \mathbf{x}_i produces no reassessments. An advantage of this method is that it is computationally efficient, but the major disadvantage is that the number of clusters must be pre-determined. Several methods exist to estimate the ideal number of clusters, which generally have the aim of finding the best compromise between minimising within-cluster variance and maximising between-cluster variance. *Coughlin and Gray [2009]* applied K-means clustering to several variables representing the stratospheric polar vortex. They used a method known as silhouette values [?] and determined the ideal number of clusters to be two (representing stable and disturbed vortex states).

- (b) **Mean-shift** clustering aims to discover ‘blobs’ in a data set. It works by updating candidates for centroids to be the mean of the points within a given region. That is, given a candidate centroid \mathbf{x}_i for iteration t , the candidate is updated according to

$$\mathbf{x}_i^{t+1} = \mathbf{x}_i^t + \mathbf{m}(\mathbf{x}_i^t), \quad (3.12)$$

where \mathbf{m} is the mean shift vector. This is calculated as

$$\mathbf{m}(\mathbf{x}_i) = \frac{\sum_{\mathbf{x}_j \in N(\mathbf{x}_i)} K(\mathbf{x}_j - \mathbf{x}_i) \mathbf{x}_j}{\sum_{\mathbf{x}_j \in N(\mathbf{x}_i)} K(\mathbf{x}_j - \mathbf{x}_i)}, \quad (3.13)$$

where $K(\mathbf{x}_j - \mathbf{x}_i)$ is a kernel function which determines the weight of nearby points. Typically, and in Figure 3.5(b), a Gaussian kernel is used, $K(\mathbf{x}_j -$

$\mathbf{x}_i) = e^{-c\|\mathbf{x}_j - \mathbf{x}_i\|^2}$. $N(\mathbf{x}_i)$ represents the set of points for which $K(\mathbf{x}_i) \neq 0$. This shifting is repeated until \mathbf{m} converges. Following this calculation, the candidates are then filtered to remove near duplicates. The greatest advantage of this method is that it automatically sets the number of clusters, so no prior assumptions about the data set are required. A disadvantage is that it requires multiple nearest neighbour searches during each iteration, and so may not be scalable to large data sets. In Figure 3.5(b) the number of clusters was determined to be four.

- (c) **Hierarchical** clustering proceeds by calculating a series of nested clusters. To begin with, all data points are considered each as a separate cluster and then at each iteration the nearest two clusters are merged. There are a number of methods to identify the distance between clusters when those clusters consist of more than one member. Following *Hannachi et al.* [2010] the *complete-linkage* method; defining the distance as the largest distance between members in the two groups. As with the K -means clustering, the number of clusters desired must be pre-determined, otherwise the algorithm will run to completion with a single cluster consisting of all data points. Again, many methods exist to determine the optimum number of clusters. *Hannachi et al.* [2010] used the gap statistic method [*Tibshirani et al.*, 2001] with vortex area, centroid latitude, and aspect ratio moment diagnostics, and found a slight preference for three clusters. As such, three clusters are used in Figure 3.5(c).

Figure 3.5 demonstrates that the three clustering methods produce very different results. As well as the size and extent of the clusters, there is also disagreement between this and past studies on the optimum number of clusters; *Coughlin and Gray* [2009] found two clusters using a silhouette values method, *Hannachi et al.* [2010] found three clusters using the gap statistic, while the mean-shift algorithm applied here produces four clusters. Further sensitivity tests were performed by randomly removing 1% of the data and re-calculating the clustering. It was found that very different clusters were calculated with this small alteration to the data, suggesting that these clusterings may not be robust if applied to different data

3.3. DATA AND METHODS

sets, such as climate model simulations. The likely reason for this sensitivity is that the data itself is not highly clustered; as can be seen in Figure 3.3 no clear bimodality is present. Rather, it is more appropriate to view the split and displaced vortex states as the tails of a distribution rather than distinct clusters or regimes.

For the reasons above, clustering methods are deemed inappropriate for the present study, and a simpler, more robust, thresholds-based method is introduced. Days with an aspect ratio > 2.4 (11% of all days) or a centroid latitude $< 66^\circ\text{N}$ (5% of all days) are classified as split and displaced states respectively. A small number of days lie beyond both thresholds, and these are classified as a mixed state (1% of all days). The vast majority of days (83%) lie in the stable state, where neither threshold is exceeded. The choice of thresholds is somewhat subjective but the results presented below are not sensitive to the exact choice of threshold. They were chosen to give a similar frequency of split and displaced vortex events (identified using the method below) as CP07 and M13.

Mitchell et al. [2011a] found that the aspect ratio and centroid latitude follow an extreme value distribution [*Coles*, 2001] and it is noted that both thresholds chosen here lie beyond the extreme value thresholds of their respective distributions (these were found to be 2.3 for aspect ratio and 72°N for centroid latitude). Some theoretical motivation for the aspect ratio threshold can also be provided by the theoretical stability of an idealised elliptical vortex. *Love* [1893] found that the Kirchoff ellipse (an elliptical patch of uniform vorticity in a quiescent fluid) is linearly unstable if the aspect ratio exceeds 3. The aspect ratio threshold of 2.4 used here lies below this limit, and so under this idealised model it might expect that some split vortex events do not display a full separation into two vortices.

Having classified each day into these four groups, a persistence criterion is introduced in order to identify split and displaced vortex *events*. A displaced vortex event requires the centroid latitude to remain equatorward of 66°N for 7 days or more, while a split vortex event requires the aspect ratio to remain higher than 2.4 for 7 days or more. The onset date is defined as the day that the appropriate threshold is first exceeded, and to ensure that no events are counted twice, these onset dates are required to be spaced at least 30 days apart, chosen

No.	Event onset	Event type	ΔT_{10} (K)	\bar{U}_{10} (m s ⁻¹)

Table 3.1: A summary table of displaced (D) and split (S) vortex events, identified from 10 hPa geopotential height data from 1958-2009. ΔT_{10} represents the mean area-weighted 50°-90°N cap temperature anomaly at 10 hPa calculated 5 days either side of the event onset date. \bar{U}_{10} represents \bar{U} at 60°N and 10 hPa averaged over the same period. Asterisks (*) represent those numbers that do not coincide (i.e. within 10 days and of the same type) with events defined by CP07 and daggers (†) events which do not coincide with events of M13.

3.3. DATA AND METHODS

to reflect radiative timescales in the lower stratosphere [Newman and Rosenfield, 1997]. Using this method, 17 displaced and 18 split vortex events (listed in Table ??) are identified over the 52 winters, an average of 7 per decade. This frequency lies between the values of CP07 (6 per decade) and M13 (8 per decade). Although data is restricted to DJFM in this analysis, no measures are taken to exclude early final warmings which may occur in late March. This is motivated by the fact that these are highly dynamically driven events which may have significant impacts on the troposphere [Hardiman *et al.*, 2011]. The events defined here may therefore include some which would traditionally be classed as final warmings (i.e. the zonal-mean zonal wind does not return to westerly). For this reason, these events are not referred to as SSWs, but simply as split and displaced vortex events.

Figures 3.6 and 3.7 show geopotential height at the peak of each of the split and displaced vortex events. The peak is defined as the day with the maximum aspect ratio or minimum centroid latitude in the two weeks following the onset date of split and displaced vortex events respectively. Almost all of the split vortex events show two clearly separated vortices or a pinched vortex shape, which is approximately symmetrical about the North Pole. Two exceptions are Figures 3.6 (a) and (k), in which the vortex is highly elliptical but not clearly split. Figure 3.6(n) shows an event with a highly elliptical vortex that is also somewhat displaced from the pole, indicating that it has some displaced nature. The majority of split vortex events are seen to occur along the 90°E-90°W axis, in line with the climatological wave-2 pattern [Andrews *et al.*, 1987]. Figure 3.6(h) shows an exception to this, with an orientation orthogonal to the majority of events.

The displacement events mostly show a smaller and weaker vortex, owing to the fact that they are more common later in winter (see Figure 3.8). Some events, particularly those occurring in late March, are also likely to be events which would traditionally be defined as final warmings. It can be seen that the majority of displacement events occur in the direction of the 0-90°E quadrant, again in line with the climatological wave-1 pattern. However, there are some exceptions to this, for instance Figures 3.7 (c) and (i), which show a westward-displaced vortex.

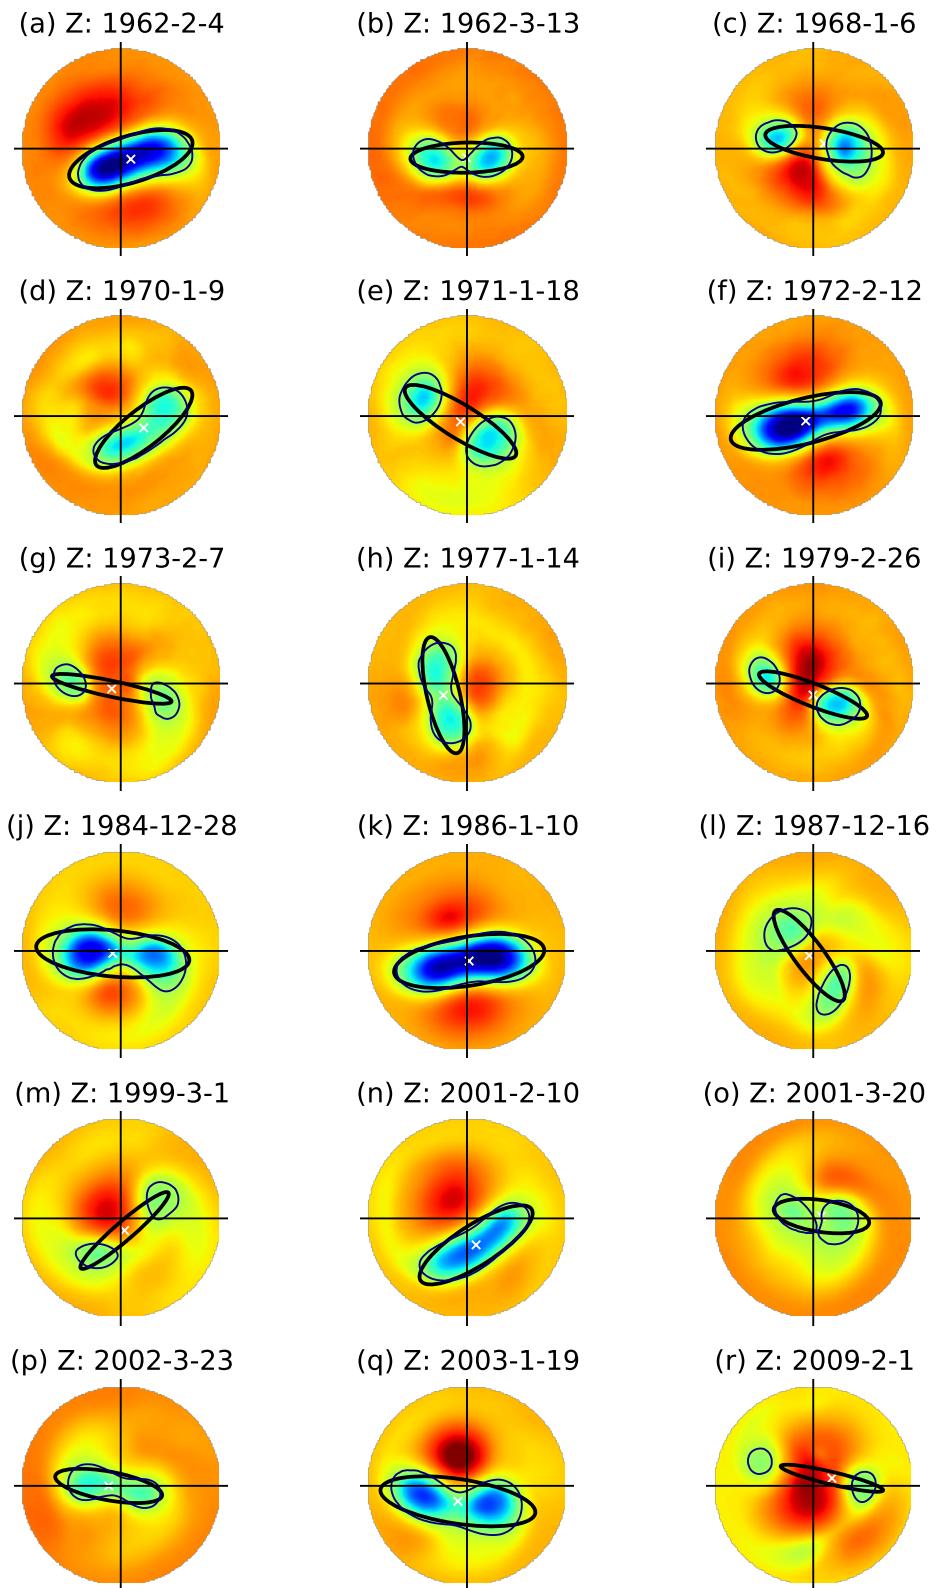

Figure 3.6: 10 hPa geopotential height at the peak of each of the 18 split vortex events identified in ERA. The peak is defined as the day with the largest aspect ratio during the two weeks following the onset date. The vortex edge is shown as a thin black contour, the equivalent ellipse the thick black contour and its centroid as a white cross. Data are transformed to cartesian coordinates with a polar stereographic projection.

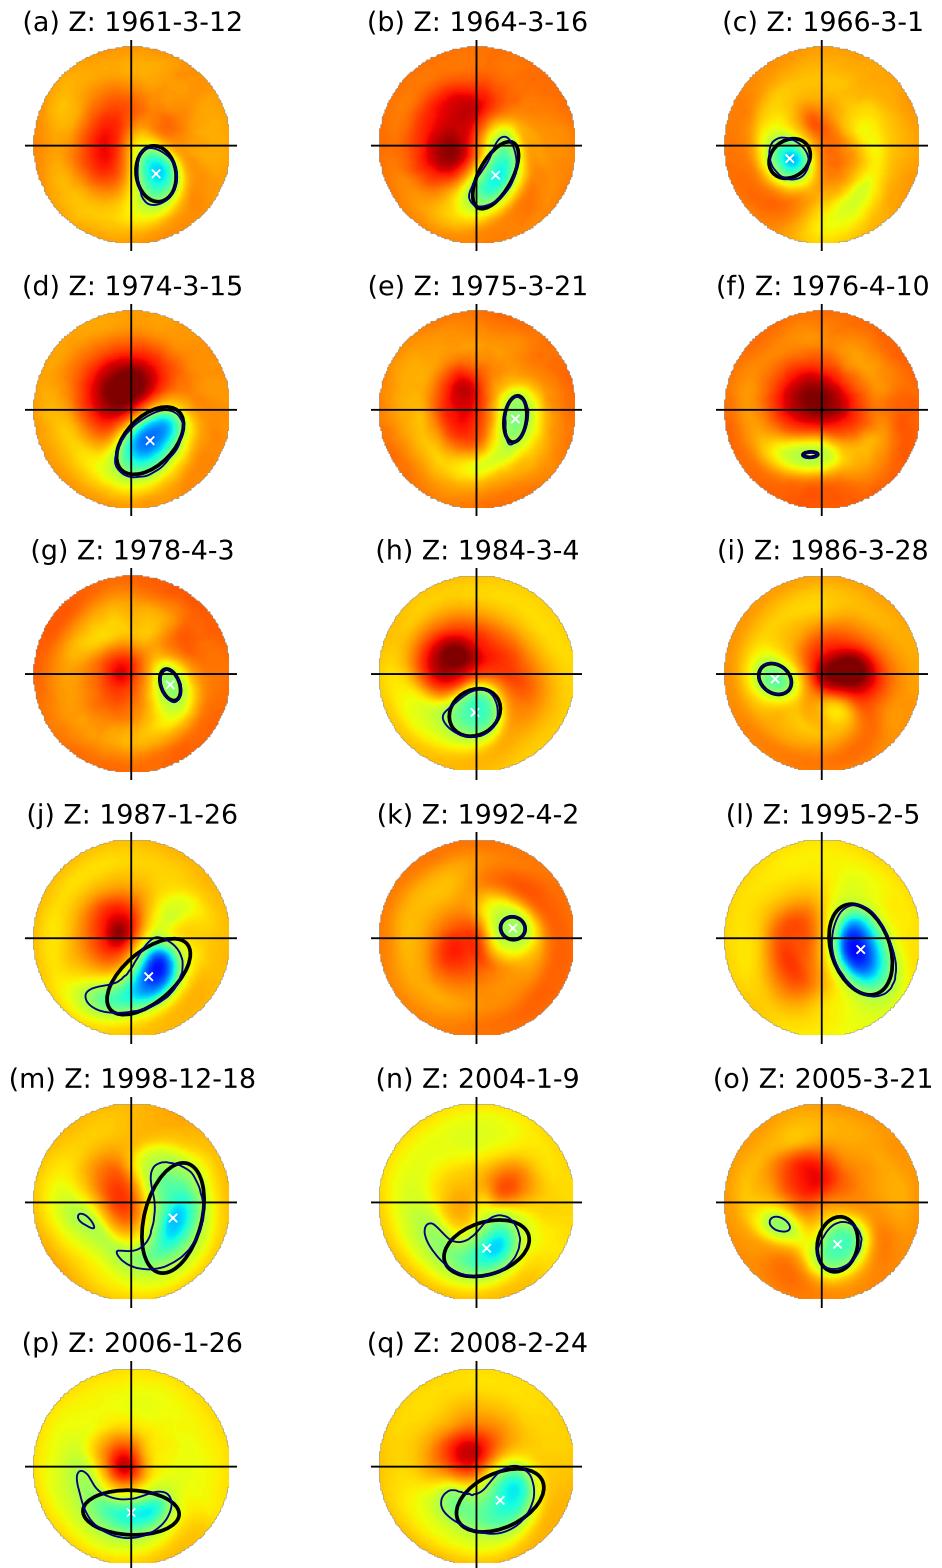

Figure 3.7: As Figure 3.6 but for the 17 displaced vortex events identified in ERA.

3.3.4 Comparison with CP07 and M13

The split and displaced vortex events identified using the above method are now compared with those of the CP07 and M13 methods. Table 3.1 identifies those events which do not coincide with the events of CP07 and M13, where ‘coincide’ is taken to mean events within 10 days and of the same type. Of the 35 events identified, 16 were found not to coincide with events of CP07 (10 displacement and 6 split). Six events were found not to coincide with those of M13 (3 displacement and 3 split), although this comparison only covers the 28 events from 1958-2002, as it was not possible to reproduce the M13 method over the longer period studied here because of the difficulties with hierarchical clustering discussed in Section 3.3.3. Just two completely new events were identified (i.e. not coinciding with either CP07 or M13); these are the displaced vortex events with onset dates 1978-3-25 and 1995-2-2.

Table 3.1 also shows polar cap averaged 10 hPa temperature anomalies (ΔT_{10}), averaged 5 days either side of the event to give a measure of the event magnitude. The events of CP07 show a larger average anomaly than events identified with the current method, although the two are not statistically significantly different: CP07 average 8.6 K [6.1, 10.9] split and 7.8 K [5.5, 9.9] for displaced vortex events, while the current method averages 5.7 K [3.0, 8.3] for split and 6.8 K [5.5, 8.2] for displaced vortex events (numbers in square brackets represent the 95% uncertainty range, calculated using a bootstrap test). It can be seen that while the vast majority of events show positive values of ΔT_{10} (i.e. warming), four events show negative values. All of these events are also identified by M13, and they attributed the negative values to the presence of a strong, cold vortex prior to the event. Zonal-mean zonal wind at 60°N and 10 hPa (\bar{U}_{10}), averaged over the same period is also shown in Table 3.1. The majority of events show negative values, in line with the traditional wind reversal criterion, although some show positive values. This again may result from a strong vortex prior to these events, as well as the fact that the current method may detect events with a distorted but strong vortex.

3.3. DATA AND METHODS

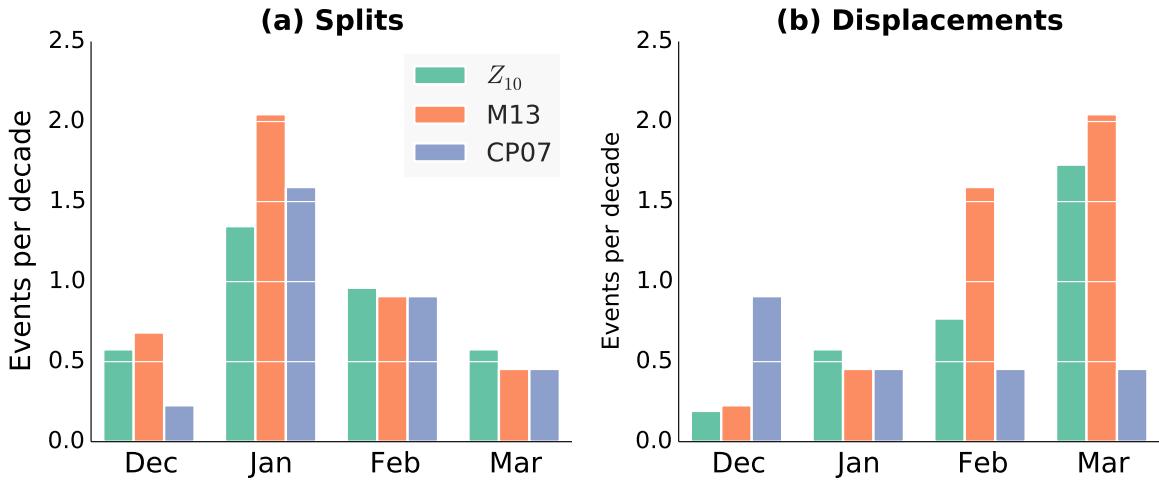

Figure 3.8: Histogram of the seasonal distribution of displaced and split vortex events, from the current (Z_{10}) method, M13 and CP07.

The seasonal distribution of split and displaced vortex events identified by the current method (Z_{10}), M13, and CP07, is shown in Figure 3.8. In all three methods split vortex events are more frequent in early-mid winter, with a peak in January. For displaced vortex events, both the current method and M13 show a skew towards events occurring later in winter. However, there is less similarity with the CP07 distribution of displaced vortex events. CP07 indicates an approximately flat distribution throughout winter, and many fewer displaced vortex events overall. It should be noted that the seasonal distribution of split vortex events from the moment based methods does not arise from the underlying climatology of aspect ratio, which remains approximately constant throughout winter (e.g., Figure 4.2). The centroid latitude does however, show a small equatorwards trend throughout winter, which may to some extent account for the seasonal distribution of displaced vortex events [Mitchell *et al.*, 2011a].

Figure 3.9 compares the average shape of the stratospheric polar vortex following the split and displaced vortex events identified by the three methods. Composites of PV in the mid-stratosphere (850 K) are shown averaged 5 days following each event. For the split vortex events, the current method (Z_{10}) method clearly shows two separated vortices, one centred over Canada and the other over Siberia. For the M13 events the split vortex composite shows the vortex stretched across the same 90°W–90°E line, although not as clearly split, while the composite

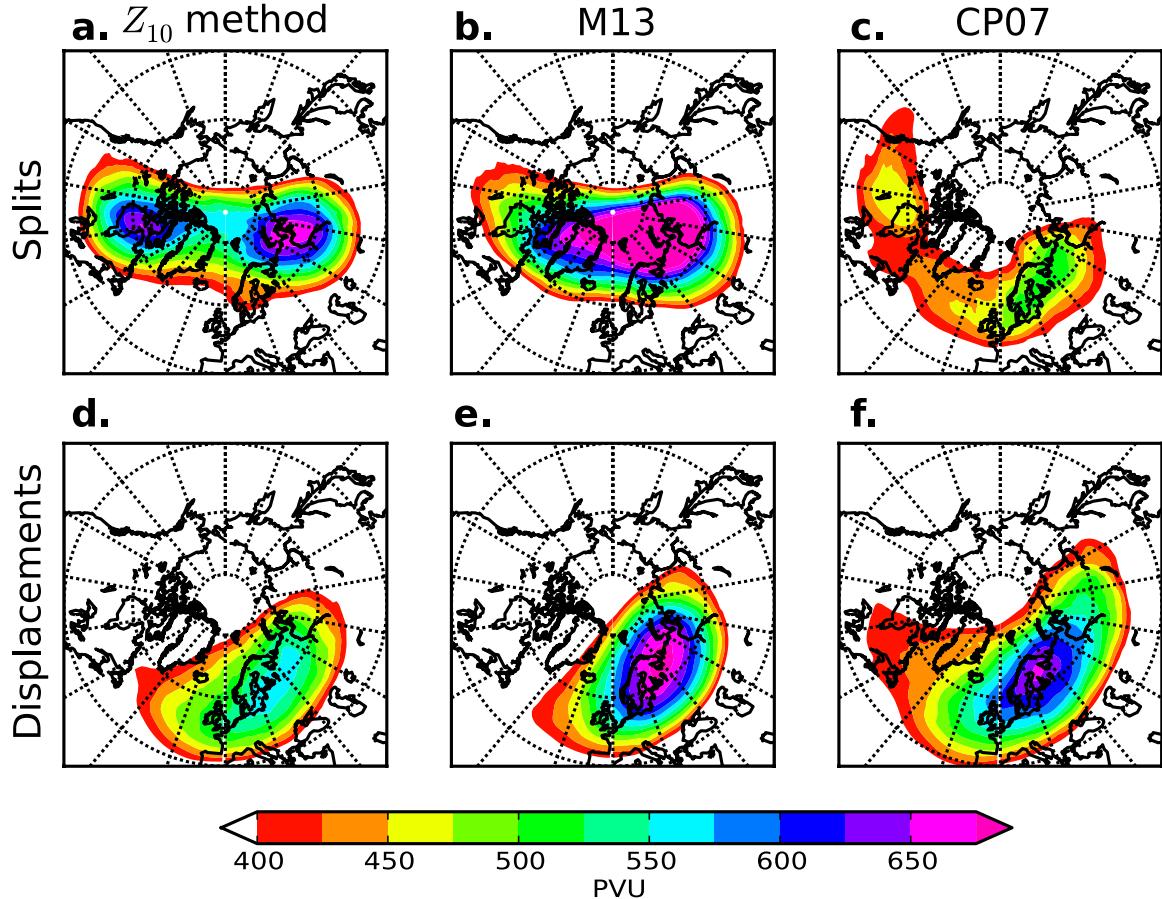

Figure 3.9: Composites of potential vorticity at the 850 K isentropic surface from the ERA reanalysis over 1958–2009. Composites are taken over the 5 days following the onset date of split vortex events (a,b,c) and displaced vortex events (d,e,f). The current (Z_{10}) method (a,b) is compared with that of M13 (b,e) and CP07 (c,f).

for the CP07 events looks very different. This has a weak vortex centred over Canada, with the other over Northern Europe in a similar location to the composite for displaced events. All three composites for displaced events show a vortex centred over Northern Europe, but this extends most westward in the CP07 composite, suggesting that there may be some contamination from misdiagnosed split vortex events.

Overall, Figure 3.9 demonstrates that the current method succeeds (in a composite sense) in identifying displaced and split vortex events at least as well as the methods of M13 or CP07. When comparing the three methods, CP07 is the clear outlier. This is most likely because the CP07 approach employs a zonal-mean threshold which cannot accurately capture some extreme events (as discussed in

3.4. INFLUENCE ON THE TROPOSPHERE

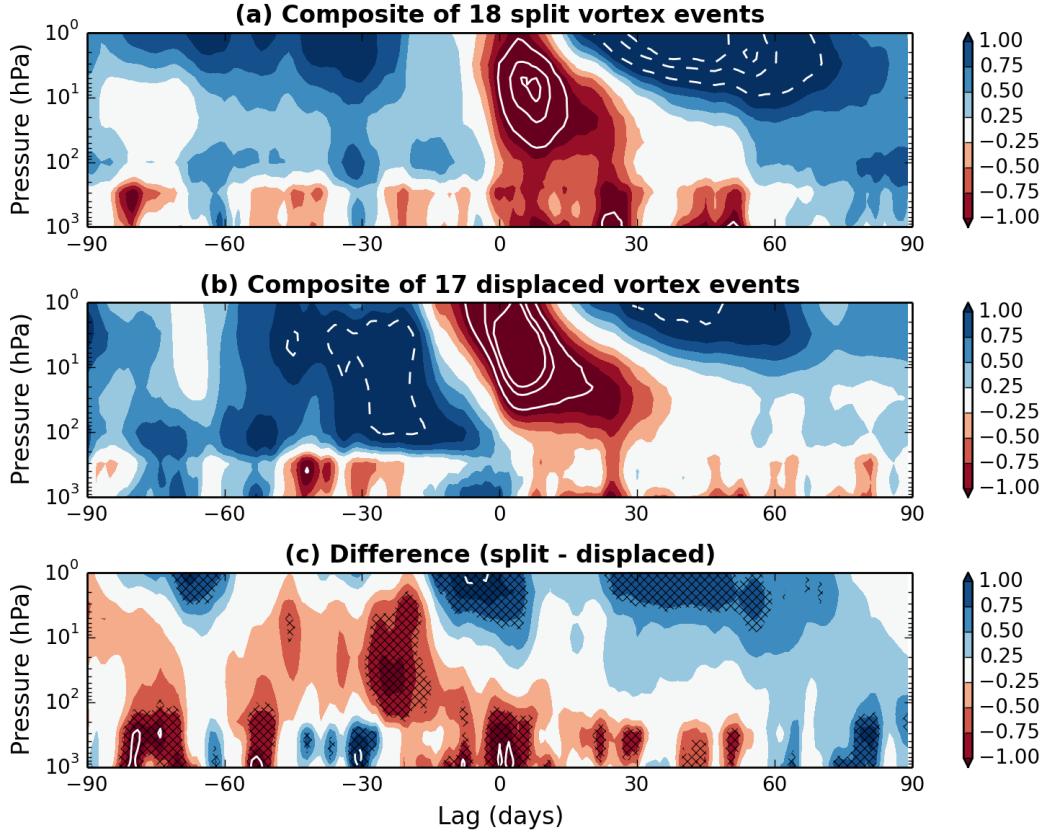

Figure 3.10: Composites of the time-height evolution of the NAM during (a) 17 vortex displacement events and (b) 18 splitting events. (c) shows the difference in these composites, and hashed regions represent those that are 95% significant according to a two-tailed bootstrap test. Lag 0 is at the onset of an event as measured at 10 hPa. Contour intervals are 0.25 and the region between -0.25 and 0.25 is unshaded. Data is from the ECMWF Reanalyses 1958–2009.

M13).

3.4 Influence on the troposphere

Having verified that this new method identifies split and displaced vortex events as skillfully as previous methods, it is now possible to study their influence on the troposphere. This is motivated by the result of M13 who, as discussed in Section 2.4.1, found tropospheric anomalies to be larger following split vortex events than displaced vortex events. Figure 3.10(a,b) shows time-height composites of the NAM over the 90 days following split and displaced vortex events. Here the method of *Baldwin and Thompson [2009]* is used to define the NAM as the lead-

ing empirical orthogonal function (EOF) of daily wintertime (November-April) zonal mean geopotential height anomalies poleward of 20°N. The anomalies are calculated by subtracting the seasonal cycle which has been smoothed with a 90-day low-pass filter. The daily NAM anomalies are then determined by projecting daily geopotential anomalies onto the leading EOF patterns. Finally, the NAM is normalised at each level so that the entire time series has unit variance.

In agreement with M13, it can be seen that the tropospheric NAM is more negative during the 60 days following split vortex events than displaced vortex events. Also similar to M13 is the fact the vertical evolution for the two events greatly differs, with split vortex events occurring almost instantaneously throughout the depth of the atmosphere and displaced vortex taking almost two weeks to propagate through the stratosphere. The near-barotropic nature of split vortex events suggests that resonant excitation of the barotropic normal mode [*Esler and Scott, 2005*] is an important influence in this case.

The difference in the NAM composites (split minus displaced) is shown in Figure 3.10(c). Statistical significance in this difference is calculated with the null hypothesis that there is no difference between the NAM response to split and displaced vortex events, and assessed using a two tailed bootstrap test with the following procedure:

- i. The labels ‘split’ and ‘displacement’ are randomly re-assigned to the 35 events.
- ii. NAM composites and the composite difference of these randomly assigned events are calculated.
- iii. The above steps are repeated 10 000 times, to form a distribution of random composite differences. If the true composite difference lies $< 2.5\%$ or $> 97.5\%$ within this distribution, then it can be said to be 95% significant.

Some significant differences are seen between the split and displaced vortex composites. For instance, a more negative stratospheric NAM is seen to precede displaced vortex events, while the dipole in the upper stratospheric and tropospheric NAM near lag 0 represents the difference in baroclinicity of the two types of event.

3.4. INFLUENCE ON THE TROPOSPHERE

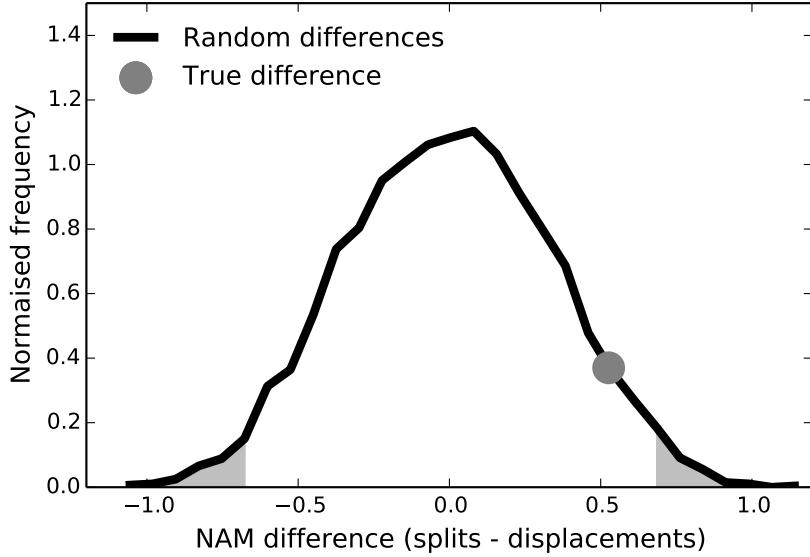

Figure 3.11: Distribution of 0-30 day mean NAM composite differences between split and displaced vortex events, formed by randomly shuffling the labels ‘split’ and ‘displacement’ between events. The 95% significant region (according to a two-tailed test; i.e. < 2.5% and > 97.5%) is shaded and the true composite difference is at the 94th percentile.

Some regions of significant differences are seen in the tropospheric NAM from 0-60 days, but there are also some regions that are not significant. Care must be taken when interpreting the importance of small significant regions these may arise by chance, even if no physical relationship exists.

The difference in the tropospheric anomalies following split and displaced vortex events is tested more robustly by examining surface anomalies averaged over the 30 days following onset. This difference is again tested using the bootstrap procedure outlined above. The distribution of randomly calculated composite differences along with the true composite difference is shown in Figure 3.11. It can be seen that the true NAM difference does not lie in the 95% significant region, so the null hypothesis that there is no difference between anomalies following split and displaced vortex events cannot be rejected. It should be noted that the statistical test here is different to that carried out by M13. They tested whether the surface NAM following split and displaced vortex events were different from randomly selected winter dates, finding that anomalies following splits are, but those following displacements are not. They did not, however, test the *difference* between split and displaced vortex events.

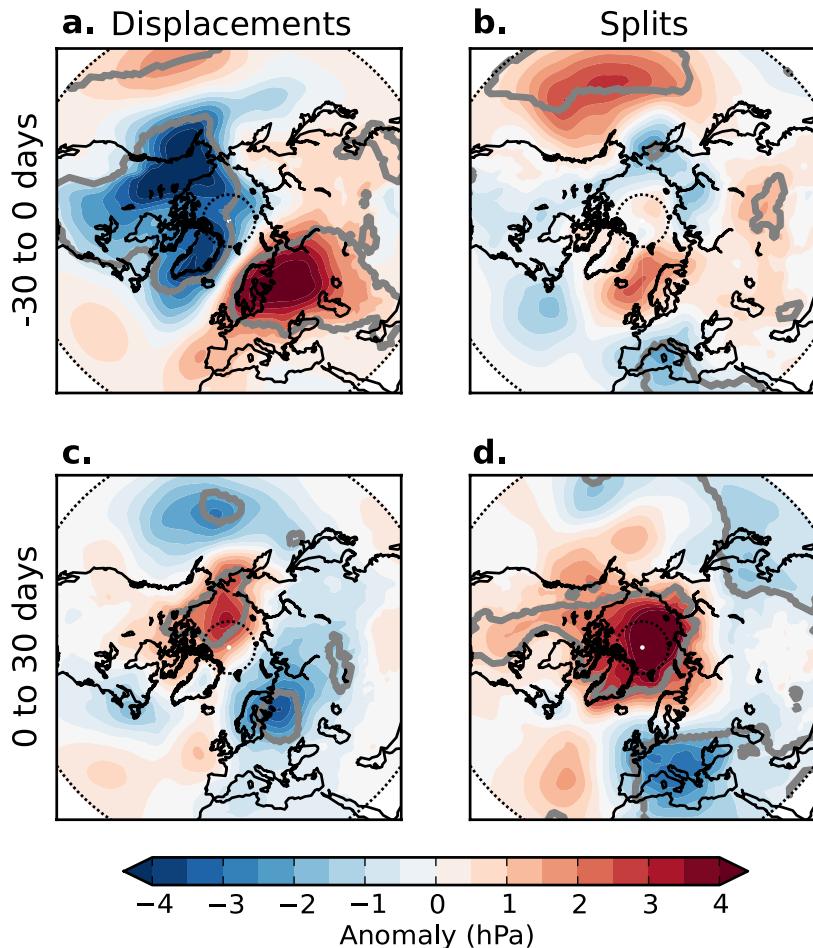

Figure 3.12: Composites of mean sea-level pressure anomalies in the 30 days before (a,b) and 30 days after (c,d) the onset dates of displaced (a,c) and split (b,d) vortex events from the Z_{10} method. Data is from the ECMWF reanalyses (1958–2009). Anomalies are calculated for each day and gridpoint from the climatology for that day of the year and gridpoint. Grey contours indicate regions of greater than 95% statistical significance according to a bootstrap significance test.

3.4. INFLUENCE ON THE TROPOSPHERE

The NAM does not provide the full description of surface variability, and so in Figure 3.12 composites of MSLP 30 days before and 30 days following the onset dates of displaced and split vortex events are presented. Statistical significance is calculated against the null hypothesis that anomalies before and after split and displaced vortex events are indistinguishable from other winter dates. This is again estimated from a two-tailed bootstrap test, in which 10 000 composites of equal size are formed from randomly selected winter dates, and the percentile of the true composite calculated from this distribution.

The strongest precursor is found for displaced vortex events, with a wave-1 pattern that is similar to the climatological stationary wave pattern [e.g. *Garfinkel and Hartmann, 2008*], suggesting increased wave-1 propagation into the stratosphere. However, the strongest anomalies following events occur after split vortex events, with a pattern resembling the negative phase of the NAM, though with a southern centre of action shifted towards Europe. A further difference between the split and displaced vortex composites is that their is a more negative MSLP anomaly over Scandinavia and Siberia following displaced vortex event. Overall, the main features of Figure 3.12 compare very well with the corresponding diagnostics from M13.

The mechanism of the stratosphere's influence on the troposphere proposed by *Ambaum and Hoskins [2002]* states that changes in the PV near the tropopause affect the tropopause height and induce tropospheric anomalies below (more details are given in Section 2.4.3). In order to investigate this mechanism, composites of tropopause height over the 10 days before, 10 days after, and 10-20 days after split and displaced vortex events are shown in Figure 3.13. The measure of tropopause height used is that of *Wilcox et al. [2012a]*, who construct a blended thermal and dynamical tropopause. Significance is again calculated using a two-tailed bootstrap test.

In line with the MSLP anomalies shown in Figure 3.12, tropopause height anomalies are seen to be larger prior to displaced vortex events, with a wave-1-like structure. Following events, tropopause height anomalies are seen to approximately mirror stratospheric PV anomalies (Figure 3.9). That is, following

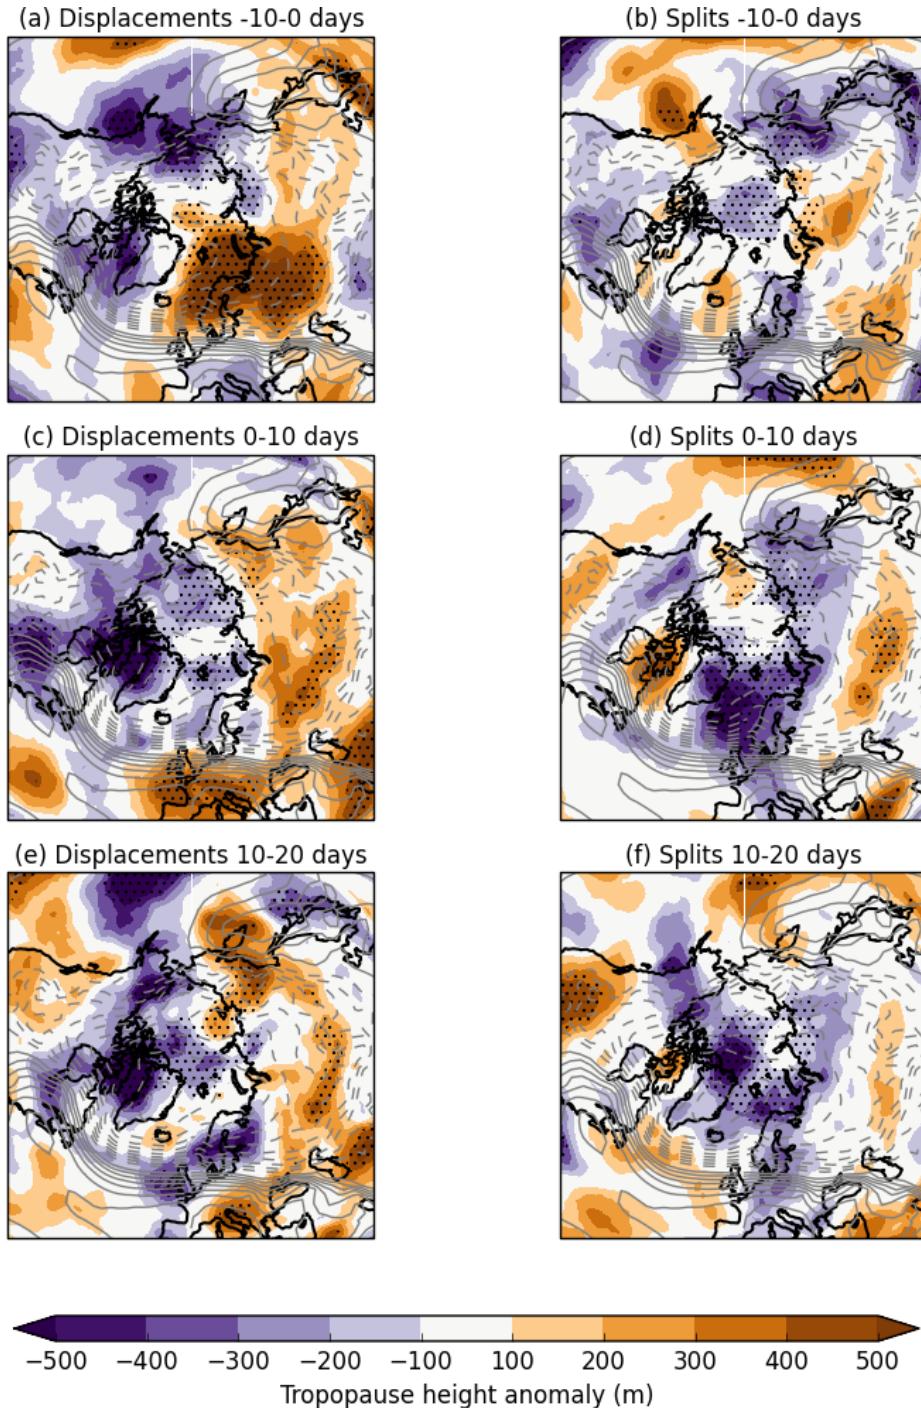

Figure 3.13: Composites of tropopause height anomalies averaged 10 days before (a,b), 10 days after (c,d) and 10-20 days after displaced and split vortex events. Anomalies are calculated for each day and gridpoint from the climatology for that day of the year and gridpoint. Stippling indicates regions of greater than 95% statistical significance according to a Monte-Carlo significance test. Grey contours indicate the first EOF of NH mean sea-level pressure, which explains 33% of the variance (dashes represent negative values).

3.4. INFLUENCE ON THE TROPOSPHERE

displaced vortex events an elevated tropopause is seen over Europe and Scandinavia, with a lowered tropopause over Canada, and following split vortex events two regions of elevated tropopause are present over Canada and Siberia with a depression between.

It is possible to quantitatively examine (although only approximately) whether these tropopause anomalies are consistent with changes in stratospheric PV above. Changes in tropopause pressure, Δp_{trop} , are related to changes in stratospheric PV, Δq , through

$$\Delta q \approx -q(1 + Bu) \frac{\Delta p_{\text{trop}}}{p_{\text{trop}}}, \quad (3.14)$$

where Bu is the Burger number, which is approximately equal to one for any PV anomaly [Amblard and Hoskins, 2002]. The change in tropopause height, Δh_{trop} can be calculated using the hydrostatic relation

$$\Delta h_{\text{trop}} = -\frac{\Delta p_{\text{trop}}}{p_{\text{trop}}} \frac{RT_{\text{trop}}}{g}, \quad (3.15)$$

where T_{trop} is the tropopause temperature. Hence

$$\Delta h_{\text{trop}} = \frac{\Delta q}{q} \frac{RT_{\text{trop}}}{g(1 + Bu)}. \quad (3.16)$$

Using a typical value of the PV change as $\sim 10\%$ (e.g., see Figure 3.9), along with $T_{\text{trop}} = 210\text{K}$, gives a change of tropopause height of $\Delta h_{\text{trop}} \approx 300\text{m}$, which is indeed approximately in line with the tropopause height anomalies seen in Figure 3.13. This, along with the fact that the pattern in tropopause height anomalies approximately mirrors that of stratospheric PV anomalies, suggests that these tropopause height anomalies are induced by changes in stratospheric PV above.

Also shown in Figure 3.13 is the surface NAM pattern (the leading EOF of DJFM daily MSLP). It can be seen that following split vortex events more than displaced (especially days 0-10), the negative tropopause height north of Iceland aligns more closely with the minimum in the NAM (this region is also a node of the NAO). This may be significant if it is expected that the fluctuation-dissipation theorem (FDT) holds in the tropospheric response to stratospheric forcing. For systems in which the FDT holds, the response of a system projected on a mode of variability should linearly scale with the projection of the forcing

on that mode [Ring and Plumb, 2008]. Under the assumption that the tropopause height perturbation represents the “forcing”, this may project more strongly on the NAM/NAO following split vortex events, consistent with a greater surface response to these events. Overall, however, the pattern correlations between the split and displaced vortex tropopause height anomalies and the NAM are not statistically significantly different because the tropopause height field is very noisy. In order to give a more detailed analysis a greater number of events would be needed.

3.5 Conclusions

Recent research has demonstrated the need to distinguish between split and displaced stratospheric polar vortex events because of their different dynamics and impacts on the troposphere. However, previous methods to identify these events are impractical for application to climate model or seasonal prediction simulations because they are highly sensitive to model climatology or rely on non-standard variables. Motivated by this, we have developed a new method to identify displaced and split vortex events which requires only geopotential height at 10 hPa. The method is summarised as follows:

- i. To identify the vortex region, a single contour of 10 hPa geopotential height is selected. This is the value of the DJFM mean zonal-mean at 60°N.
- ii. Using this contour the centroid latitude and aspect ratio moment diagnostics can be calculated.
- iii. Events are identified using a threshold criterion: Displaced events are occur if the centroid latitude remains equatorward 66°N for 7 days or more. Split events occur if the aspect ratio remains above 2.4 for 7 days or more. In order to ensure events are not counted twice, no two events may occur within 30 days.

Vortex moment diagnostics derived from geopotential height are highly correlated with those derived from PV, although fewer high aspect ratio values are seen. The

3.5. CONCLUSIONS

use of geopotential height here is motivated by the fact that it is commonly output by climate models, whereas PV is not. However, in cases where PV is available (such as in reanalyses) its use is preferable because of its quasi-conservative properties and smaller-scale features. The above method can be easily adapted to be used with PV-based vortex moments.

Analysis of the stratosphere following events identified by this method demonstrates that it is able to accurately identify split and displaced vortex events. Most of the events identified coincide with those of M13, and about half with events identified by CP07. Composite analysis indicates that the position of the stratospheric polar vortex following these events is at least as extreme as that from the previous methods.

Having identified these events, their impact on the troposphere is investigated. Composites of the NAM indicate a more negative surface NAM over the month following split vortex events than following displaced vortex events. This supports the finding of M13, using a different event identification method and extended data set. However, using a bootstrap test the composite *difference* of the surface NAM is not found to be statistically significant.

Anomalies of tropopause height following split and displaced vortex events are found to be co-located with stratospheric PV anomalies. They are also of a magnitude consistent with being induced by changes in the stratospheric polar vortex. Surface anomalies induced by changes in tropopause height may explain therefore explain the different surface anomalies following split and displaced vortex events. However, it is not possible to draw firm conclusions on this because of the relatively small number of events and the noise of the MSLP and tropopause height fields.

Overall, statistically significant results about the difference in the tropospheric response to split and displaced vortex events will require a larger number of events. This is achieved through the analysis of climate model simulations in the next chapter.

CHAPTER 3. A GEOMETRICAL DESCRIPTION OF VORTEX VARIABILITY

CHAPTER 4

Representation of vortex variability in climate models

4.1 Introduction

Over the past decade an increasing number of climate models have included a well-resolved stratosphere, with model lids above the stratopause. For example, the fifth Coupled Model Intercomparison Project (CMIP5) [Taylor *et al.*, 2012] includes 15 models with an uppermost level above the stratopause, whereas the previous intercomparison project, CMIP3, includes only five [Cordero and Forster, 2006]. The CMIP5 model simulations are significant in that they are evaluated in the the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5) [Stocker *et al.*, 2013]. This change in model stratospheric resolution has been largely motivated by an increased understanding of the stratosphere's influence on tropospheric climate (discussed in Gerber *et al.* [2012] and Chapters 2 and 3).

The effect of this greater stratospheric resolution was studied by Charlton-Perez *et al.* [2013], who compared stratospheric variability between high-top and low-top models within the CMIP5 ensemble (they defined “high-top” as a model lid above 1 hPa, and “low-top” below). They found that the low-top models have a weaker and less realistic representation of daily to interannual polar stratospheric variability than high-top models, and attributed this to the fact that the low-top

models simulate fewer SSW events than high-top. This is combined with a slightly weaker tropospheric NAM response in the two months following SSW events in the low-top compared to high-top models.

These results are supported by similar studies which compared natural variability in high and low-top versions of the same model. *Cagnazzo and Manzini [2009]* found that a high-top model gave a more realistic representation of the influence of ENSO on the NH extratropical stratosphere. Similarly, *Hardiman et al. [2012b]* showed the influence of the QBO on the extratropics as well as decadal trends in the NAO were more realistically simulated by the high-top than the low-top model. These differences have again been linked to the different simulation of SSW events in high- and low-top models [*Sassi et al., 2010*].

Other studies have compared simulations of climate change with high- and low-top models. *Huebener et al. [2007]* linked a increased weakening of the stratospheric polar vortex in high-top simulations to a more southward shift of the NH winter storm track, which in turn affects trends in North Atlantic temperatures and precipitation. *Manzini et al. [2014]* investigated climate change simulations of high- and low-top models in the CMIP5 ensemble. They found that the inter-model spread in the simulation of changes of stratospheric polar vortex winds accounts for a significant fraction of the inter-model spread of trends in the surface NAM under climate change. Interestingly, *Manzini et al. [2014]* also show that global surface temperature trends under climate change (and so climate sensitivity) are larger for high-top compared to low-top models. However, when comparing pairs of high- and low-top versions of the same (or similar) models, little in climate sensitivity difference is detected, and they conclude that this difference is unlikely to have a physical basis.

Despite these findings about the differences between high- and low-top models, it is important to note that a model lid above the stratopause is not a sufficient condition for the accurate representation of stratospheric processes or stratosphere-troposphere coupling. Indeed, *Charlton-Perez et al. [2013]* found that the frequency of SSWs in high-top CMIP5 models varies widely, from about 2.5 to 8 events per decade.

4.1. INTRODUCTION

In this chapter we apply the methods developed in Chapter 3 to evaluate the representation of stratospheric polar vortex variability in the CMIP5 climate models. Motivated by these results which demonstrate a more realistic representation of tropospheric and stratospheric climate in high-top models, we select only models with a lid height above the stratopause. In doing this we extend the work of *Charlton-Perez et al.* [2013] to consider the two-dimensional structure of the polar vortex using moment diagnostics, including the identification of split and displaced vortex events.

The only previous study to apply vortex moment diagnostics to climate model simulations is that of *Mitchell et al.* [2012]. They studied models from the second Chemistry-Climate Model Validation (CCMVal-2) project, although their analysis was limited because only three models of the 18 in CCMVal-2 provided the daily PV which was necessary for the calculation of moment diagnostics. They also did not classify split and displaced vortex events in their analysis. Using the new methods developed in Chapter 3, we are now able to calculate moment diagnostics and classify split and displaced vortex events using geopotential height from a much larger number of models.

There are three main objectives to this investigation. First, we wish to evaluate the current state of models' representation of the stratospheric polar vortex and stratosphere-troposphere coupling, including whether there are any consistent biases among models. Second, we aim to determine if there is a relationship between model parameters (such as horizontal and vertical resolution) and biases in their representation of vortex variability. This may motivate future model improvements to reduce these biases. Third, we will investigate whether the increased sample size of the CMIP5 ensemble can be used to better understand the mechanism behind the different tropospheric response to split and displaced vortex events, which was described in Chapter 3.

4.1.1 CMIP5 model simulations

For this analysis only climate models with a lid height above the stratopause are selected from the CMIP5 ensemble. In total, 13 such models were available

from 8 different modelling centres. Although another two (CESM1-WACCM and MIROC-ESM) are listed in the CMIP5 ensemble, appropriate data was not found to be available for these models in the CMIP5 archive (<http://pcmdi3.llnl.gov/esgcet/home.htm>). These models are listed in Table 4.1. It can be seen that 12 of the 13 models have an uppermost level which is in the upper mesosphere (70-80 km), but CanESM2 has a significantly lower lid which is very close to the stratopause.

Historical simulations have been used throughout this analysis. These include observed climate forcings, such as from greenhouse gasses, ozone depletion, land-use change, tropospheric and stratospheric aerosols and solar variability. The simulation period considered is limited to 1958-2005, so that it coincides with the ERA-40/ERA-Interim reanalysis period (CMIP5 historical simulations end at 2005). Limiting the model simulation analysis to the same period as observations may be important because several studies have suggested that external forcing, such as volcanic eruptions and solar variability, has a significant impact on stratospheric variability [e.g., *Kodera*, 1994; *Gray et al.*, 2010; *Mitchell et al.*, 2011b]. In order to achieve the largest possible ensemble size, all available ensemble members have been used for each model, which leads to different numbers of years entering the ensemble from different models.

4.2 Vortex mean state and variability

4.2.1 Moment diagnostics

The centroid latitude and aspect ratio moment diagnostics are calculated for each of the CMIP5 models over DJFM from the 10 hPa geopotential height field, using the method described in Section 3.3.2. For each model the value of the DJFM mean geopotential height at 60°N and 10 hPa is used to define the appropriate contour for the calculation of the moment diagnostics. This accounts for biases in the mean geopotential height between different models.

The resulting joint distributions of daily centroid latitude and aspect ratio from each of the models are shown in Figure 4.1, along with that from the ERA-

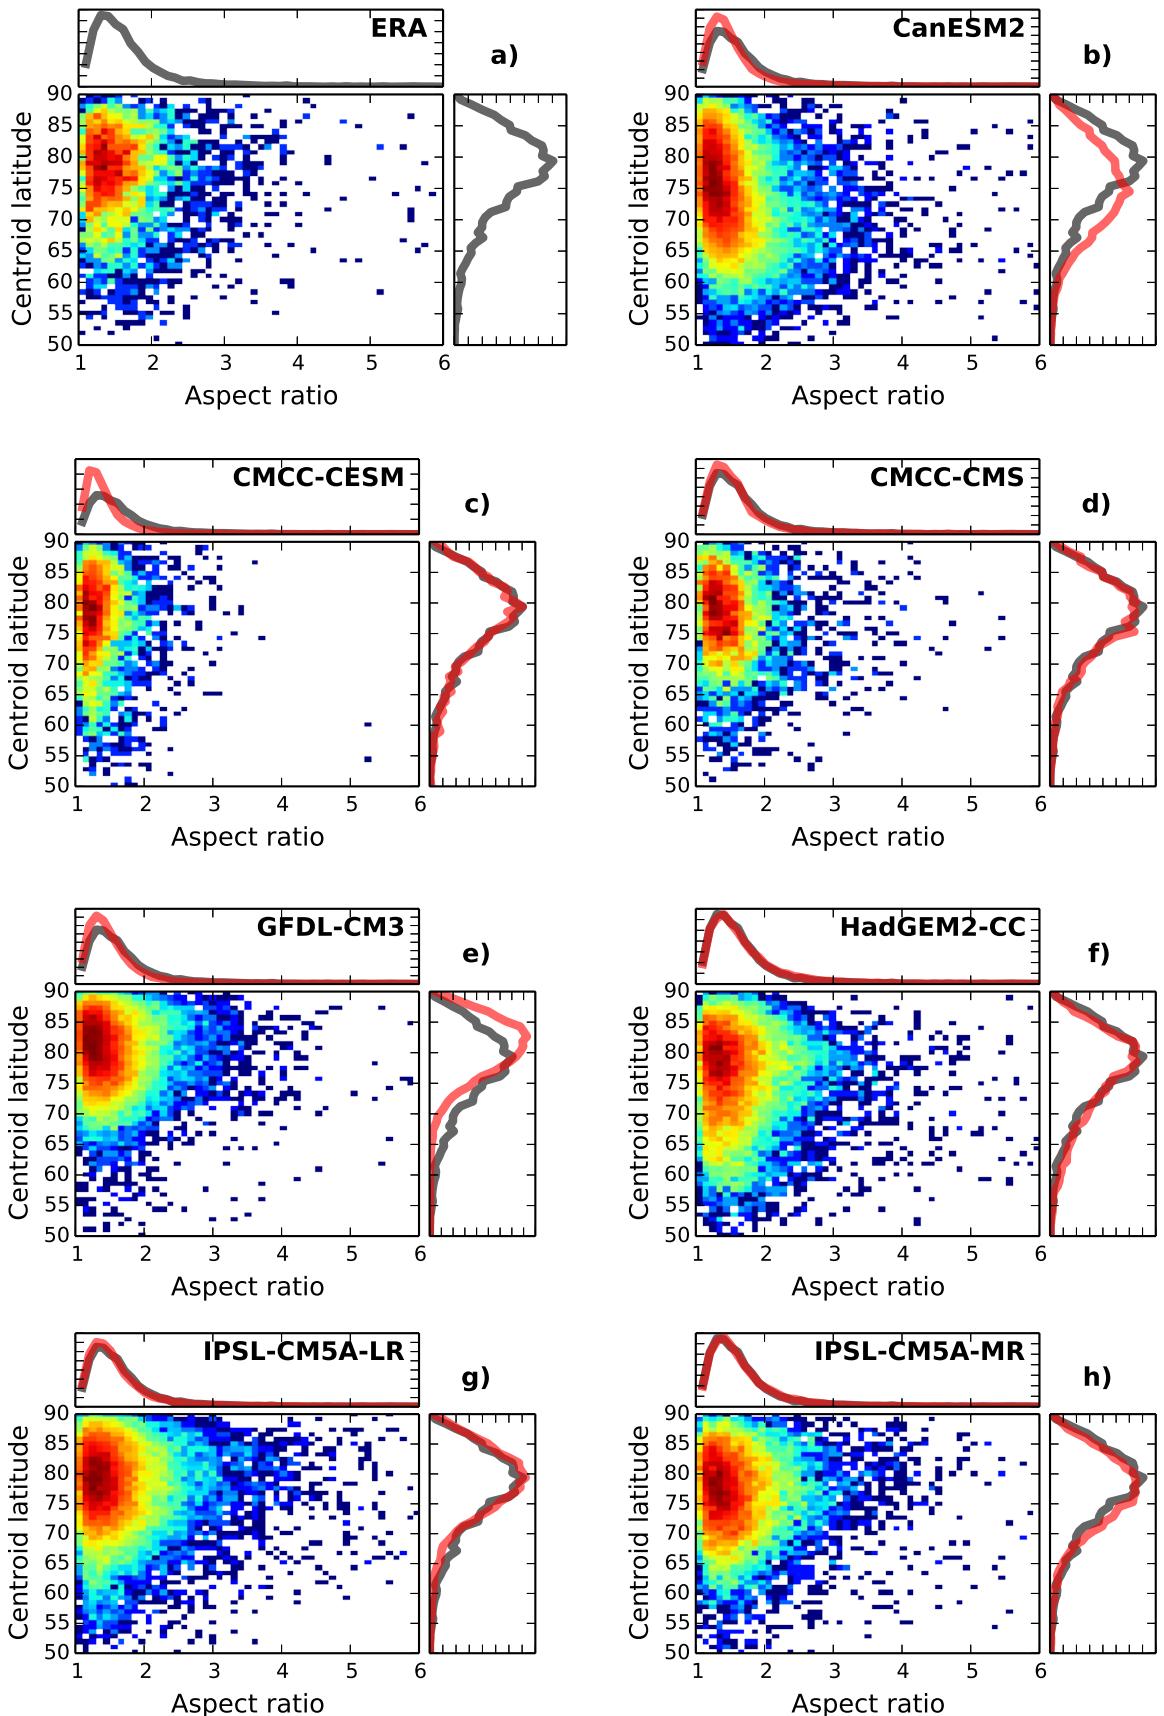

Figure 4.1: Distributions of centroid latitude and aspect ratio for the ERA (grey lines) (a) and the CMIP5 models (red lines). Joint distributions are shown with a logarithmic scale such that red squares represent the densest regions.

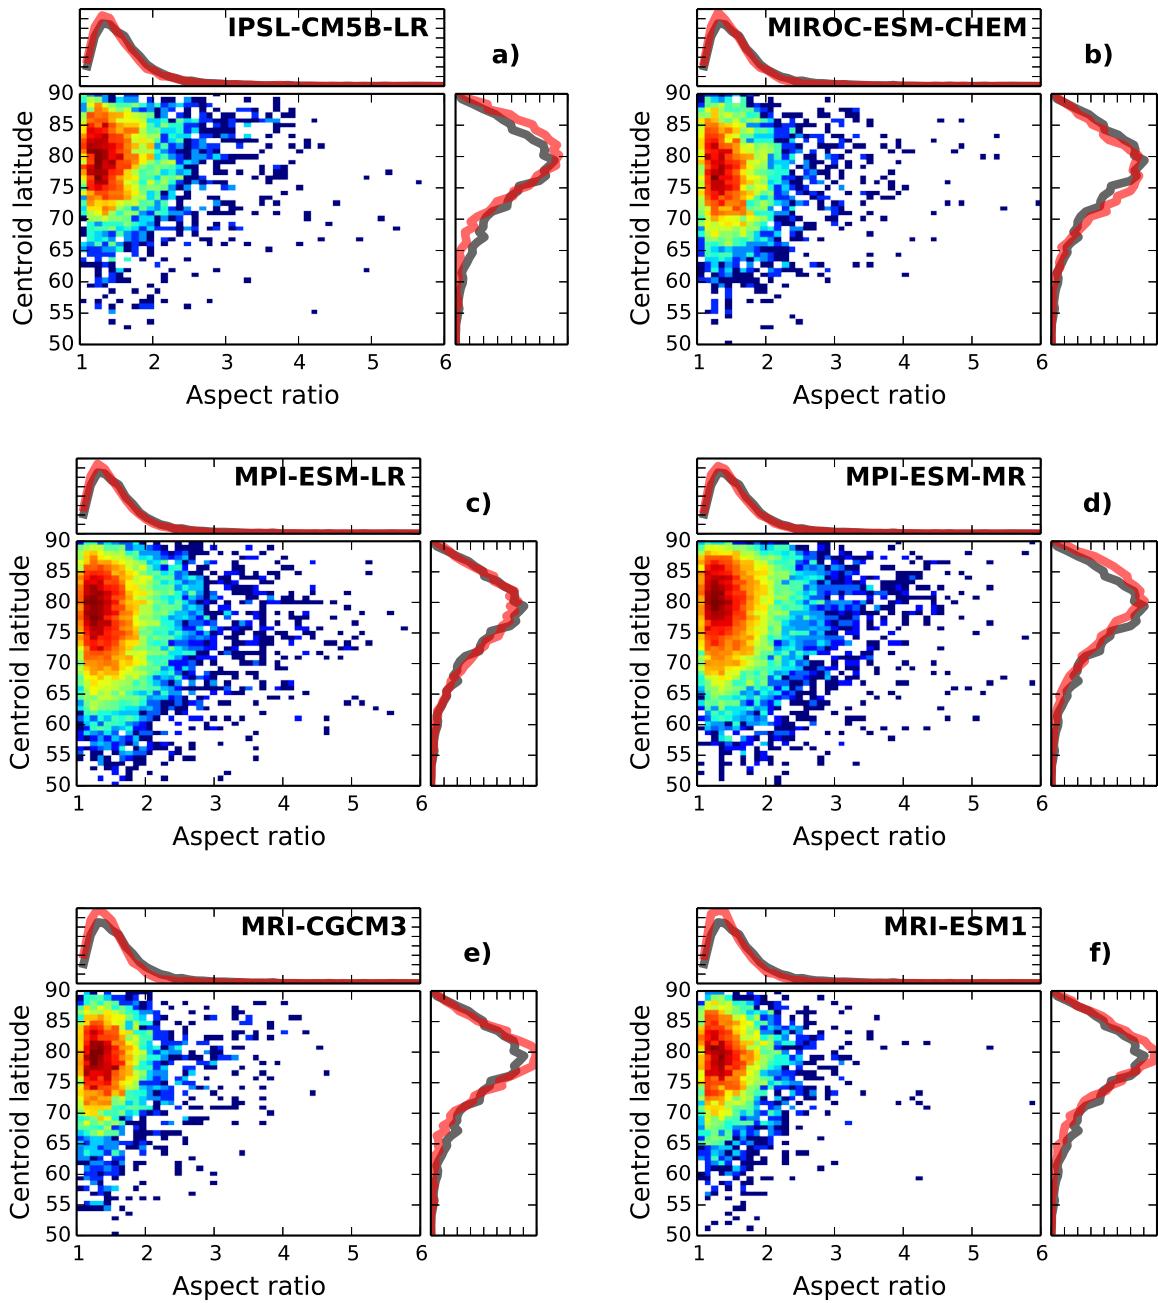

Figure 4.1: (Continued)

4.2. VORTEX MEAN STATE AND VARIABILITY

Model	Ensemble size	Lid/ km	Levels	dh/km	dz ₁ /km	dz ₂ /km
CanESM2	5	48.1	35	268	1.48	2.30
CMCC-CESM	1	80.6	39	536	1.49	1.89
CMCC-CMS	1	80.6	95	268	0.65	0.68
GFDL-CM3	5	76.3	48	191	1.32	1.75
HadGEM2-CC	3	84.1	60	144	0.82	1.18
IPSL-CM5A-LR	5	70.4	39	254	1.21	1.75
IPSL-CM5A-MR	3	70.4	39	169	1.21	1.75
IPSL-CM5B-LR	1	70.4	39	254	1.21	1.75
MIROC-ESM-CHEM	1	87.8	80	399	0.77	0.73
MPI-ESM-LR	3	80.6	47	268	0.87	1.70
MPI-ESM-MR	3	80.6	95	268	0.65	0.68
MRI-CGCM3	1	80.6	48	107	0.88	1.87
MRI-ESM1	1	80.6	48	107	0.88	1.87

Table 4.1: Parameters of the CMIP5 models studied in this chapter. Where the model lid is defined in terms of a pressure, its height was estimated using $z = -H\ln(p/p_0)$ with $H = 7$ km and $p_0 = 1000$ hPa. Following [Anstey et al. \[2013\]](#), horizontal resolution, dh, is estimated at 45°N and vertical resolution is shown averaged over two regions; 5-15 km (dz₁) and 15-30 km (dz₂).

40/ERA-Interim reanalysis (hereafter ERA) calculated in Chapter 3. For each model the joint distribution histogram is plotted with a logarithmic colour scale which is normalised according to the number of days entering each box. As discussed in Chapter 3, it can be seen that the joint distribution for ERA has an approximately triangular distribution with high aspect ratio/poleward centroid latitude, and low aspect ratio/equatorward centroid latitude being relatively more common than high aspect ratio/equatorward centroid latitude. This shape of distribution is well replicated by most of the models, although CanESM2 has a significantly different shape, with the high aspect ratio/equatorward centroid latitude being more common.

No clear consistent biases among models emerge from this analysis. CanESM2 has a modal centroid latitude which is about 5° too far equatorward compared to reanalysis. Contrastingly, GFDL-CM3 has a modal centroid latitude about 2.5° more poleward than observed. CMCC-CESM displays a clear bias in the aspect ratio, with a distribution much less skewed towards high values than in reanalysis.

The winter seasonal cycle of aspect ratio and centroid a latitude in the CMIP5

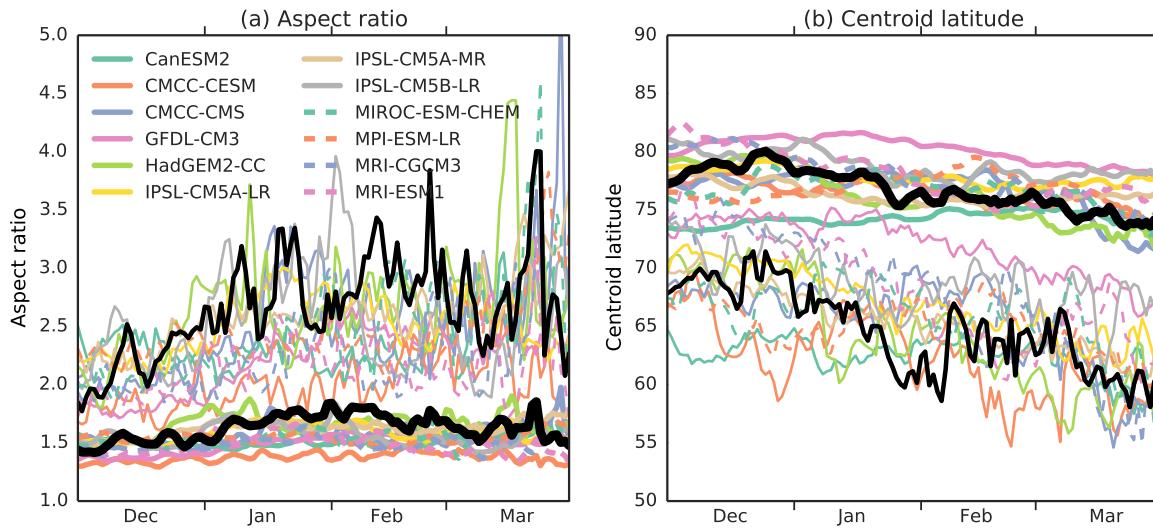

Figure 4.2: Seasonal cycle of aspect ratio and centroid latitude in ERA (black) and the CMIP5 models (colours). Thick lines represent the mean and thin lines the 95th or 5th percentile for aspect ratio and centroid latitude respectively.

models is shown in Figure 4.2. For the mean aspect ratio and centroid latitude, the majority of models agree well with reanalysis. CMCC-CESM has a consistently too low mean aspect ratio, while GFDL-CM3 has a consistently too poleward mean centroid latitude, indicating that these biases are not strongly seasonally dependent. On the other hand, the large equatorward bias in the CanESM2 mean centroid latitude is much larger in December and early January than later in winter. The 95th percentile of aspect ratio is lower than reanalysis for the majority of models throughout the season, indicating that models have, on average, too little variability in aspect ratio

4.2.2 Displaced and split vortex events

Displaced and split vortex events are identified within the CMIP5 ensemble using the threshold-based method described in Section 3.3.3. The same thresholds as used for ERA (66°N for centroid latitude and 2.4 for aspect ratio) are used for the models in order to identify, as much as possible, geometrically equivalent events. The same persistence of 7 days was also used. The frequency of displaced and split vortex events for each model is shown in Figure 4.3.

The total frequency of displaced and split vortex events for each of the CMIP5

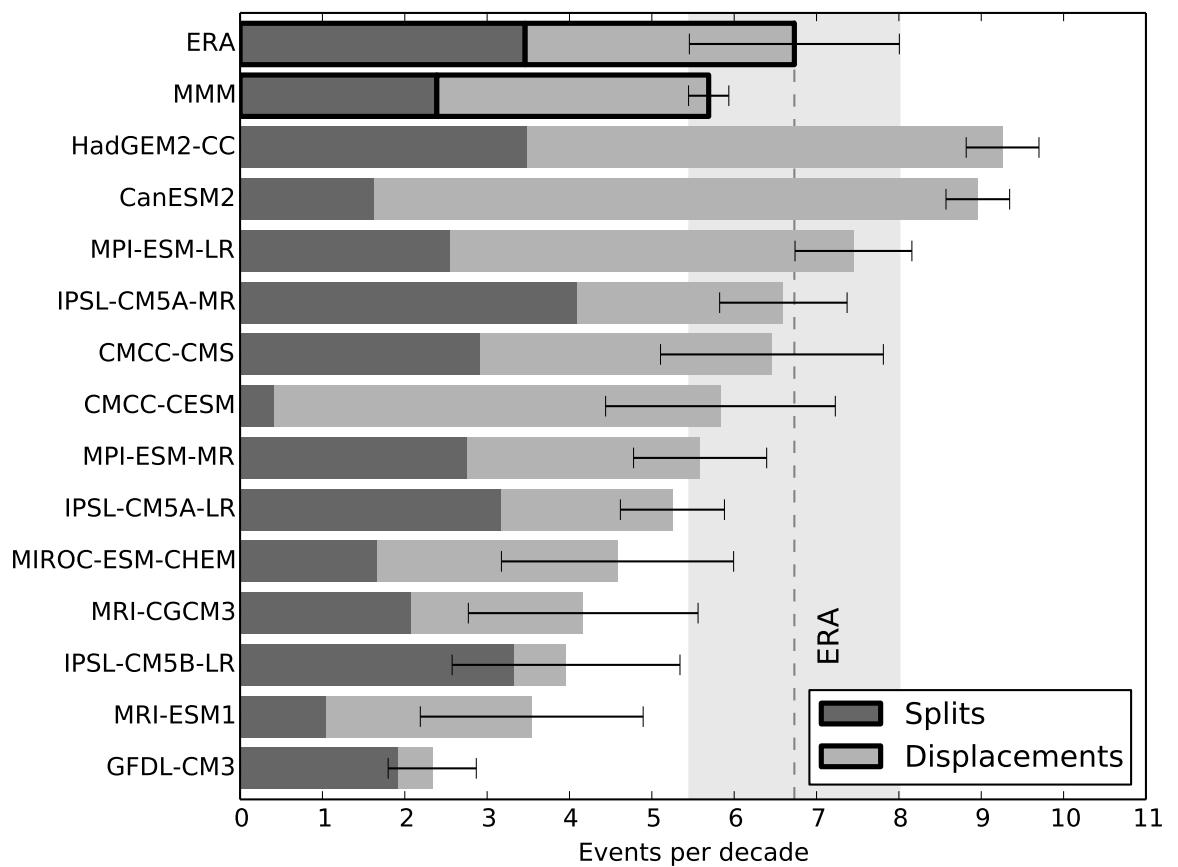

Figure 4.3: Frequency of split and displaced vortex events in the CMIP5 models, ERA, and the multi-model mean (MMM). Error bars are for the frequency of all events, and represent one σ range, assuming a binomial distribution of events. The grey shaded region represents the one σ range for ERA, along with the mean (dashed line.)

models agrees well with the equivalent SSW frequency calculated by *Charlton-Perez et al.* [2013], who identified events based on the reversal of zonal-mean zonal wind at 60°N and 10 hPa. They also found HadGEM2-CC to have the highest frequency of events within the CMIP5 ensemble, while MRI-CGCM3 is the model with the lowest frequency of SSWs in their study (excluding GFDL-CM3 and MRI-ESM1 which *Charlton-Perez et al.* [2013] did not analyse, MRI-CGCM3 is the second-lowest frequency in the present study). This similarity between *Charlton-Perez et al.* [2013] and the present study indicates that the close relationship between moment diagnostics-defined events and SSWs defined by zonal-mean zonal wind, as described in Chapter 3, also holds for climate models (although this is not explicitly studied here).

As well as the large differences in the total frequency of displaced and split vortex events, it can be seen in Figure 4.3 that the ratio of frequencies of these events varies significantly between models. For instance CanESM2 and CMCC-CESM simulate almost entirely displaced vortex events, while IPSL-CM5B-LR and GFDL-CM3 simulate almost entirely split vortex events. In the multi-model mean (MMM) these biases largely cancel, to give a approximately equal ratio of displaced to split vortex events, which is in agreement with reanalysis.

The seasonal distribution of these displaced and split vortex events is illustrated in Figure 4.4. Some models (CMCC-CMS, HadGEM2-CC and IPSL-CM5A-LR) replicate the observed distribution, with split vortex events being more likely in early winter, and displaced vortex events in late winter. Other models, however, have a very different distribution of events. CanESM2, CMCC-CESM and MPI-ESM-LR all show little seasonal variability in the frequency of events.

It is now considered how model biases in the climatology of the stratospheric polar vortex, discussed in Section 4.2.1, affect the frequency of split and displaced vortex events. The climatological average state of the vortex is defined by the mode – the peak of the probability distribution function – of the aspect ratio and centroid latitude. Unlike the mean, this quantity is not affected by extreme values and it represents the average undisturbed state of the vortex. The peak can be

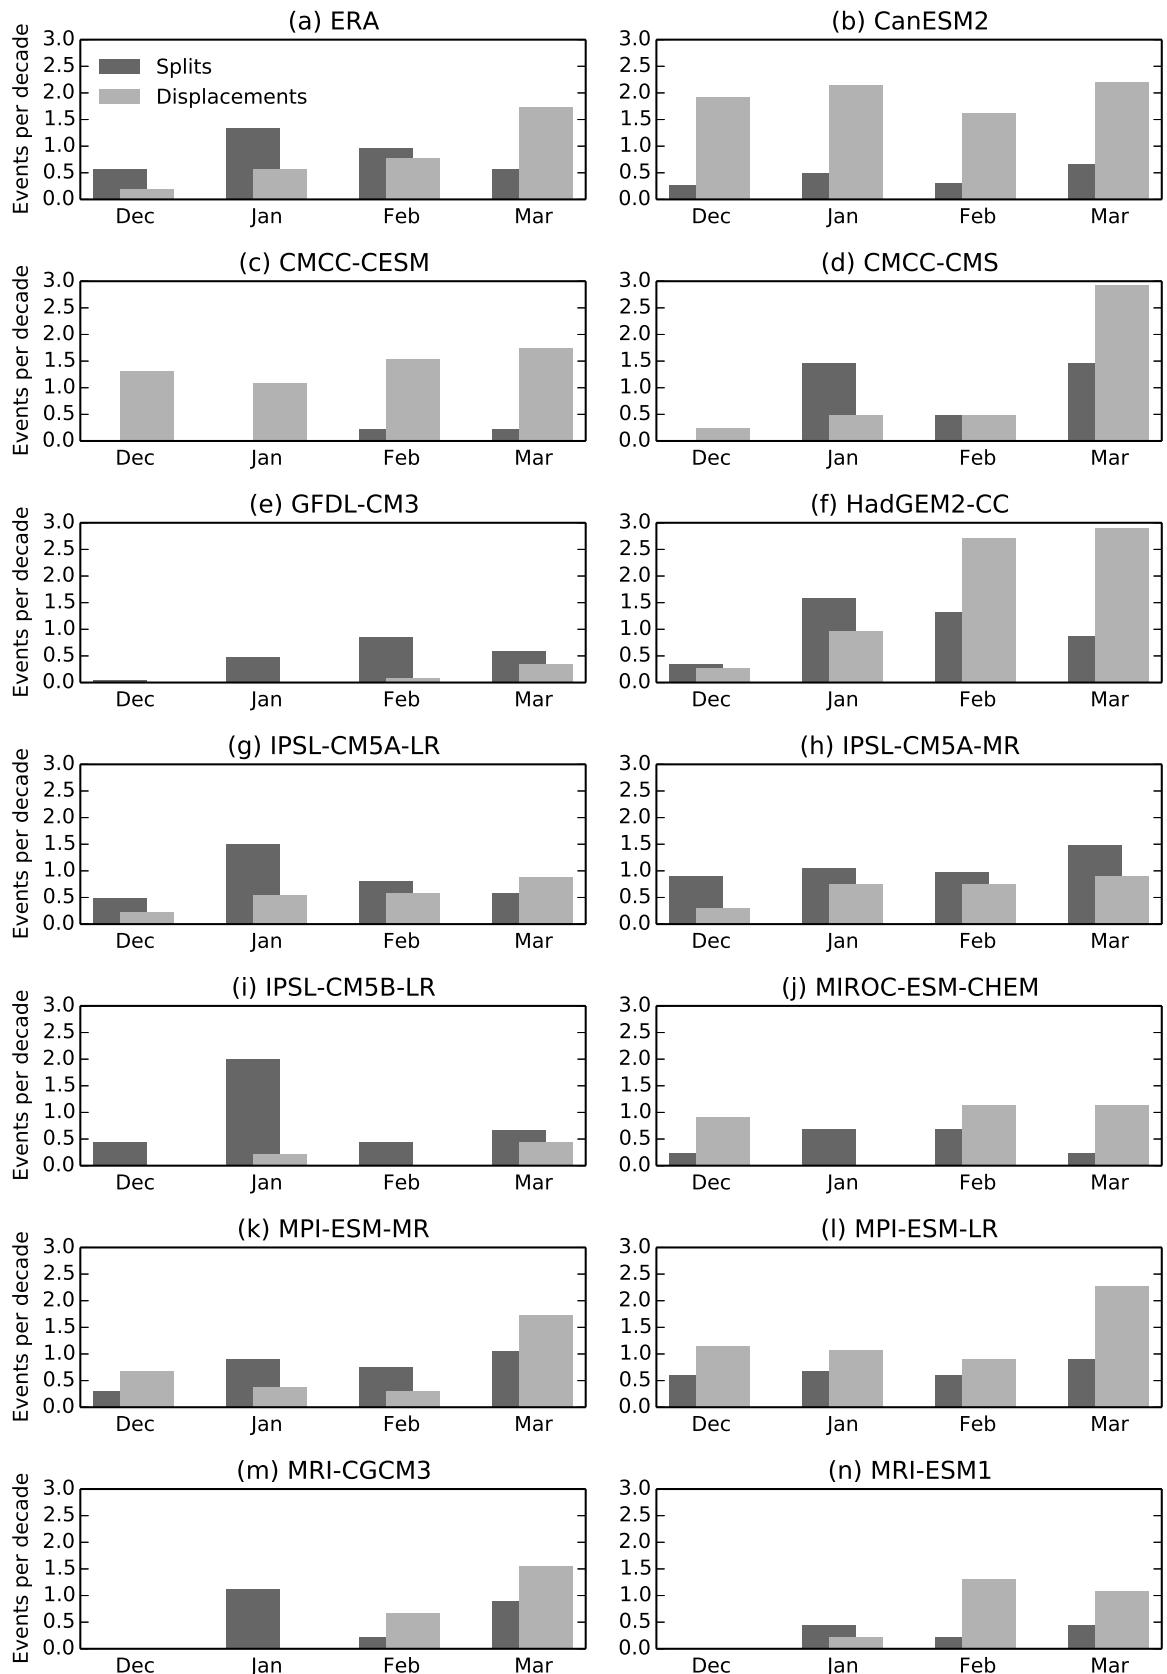

Figure 4.4: Seasonal distribution of the occurrence of split and displaced vortex events in ERA (a) and the CMIP5 models.

estimated by the maximum value of a histogram, however this introduces significant random errors and is sensitive to the selection of bin size. A more accurate estimation of the mode can be made by fitting the aspect ratio and centroid latitude with a theoretical distribution and then finding the peak of that distribution. Following *Mitchell et al.* [2011a], we fit the aspect ratio with a generalised extreme value (GEV) distribution of the form

$$f(x; \mu, \sigma, \xi) = \frac{a^{(-1/\xi)-1}}{\sigma} e^{-a^{-1/\xi}} , \quad (4.1)$$

with

$$a = 1 + \xi \frac{x - \mu}{\sigma} , \quad (4.2)$$

where μ determines the position of the peak along the x -axis, σ determines the variance of the distribution and ξ the skewness. These parameters are determined using the method of maximum-likelihood estimation [*Wilks*, 2006]. This method is also used to fit a Gaussian distribution of the form

$$f(x; \mu, \sigma) = \frac{1}{\sigma \sqrt{2\pi}} \left(-\frac{(x - \mu)^2}{2\sigma^2} \right) , \quad (4.3)$$

where μ determines the position of the peak along the x -axis and σ is the standard deviation, to the cube of the centroid latitude, and then the cube root taken to return the original distribution. *Mitchell et al.* [2011a] found that these distributions accurately fit the histograms of centroid latitude and aspect ratio in reanalysis data, apart from the extreme tails of the distribution. Qualitative inspection of the distribution for each model confirms that they also provide a similarly good fit to each of the model's histograms.

Figure 4.5 shows the relationship between the modal aspect ratio and centroid latitude and frequency of split and displaced vortex events. It can be seen that strong linear relationships exist; the modal aspect ratio accounts for 79% of the variance in the frequency of split vortex events and the modal centroid latitude accounts for 76% of the variance in the frequency of displaced vortex events. This demonstrates that biases in the average undisturbed state of the vortex account for the vast majority of inter-model spread in the representation of extremes. An

4.2. VORTEX MEAN STATE AND VARIABILITY

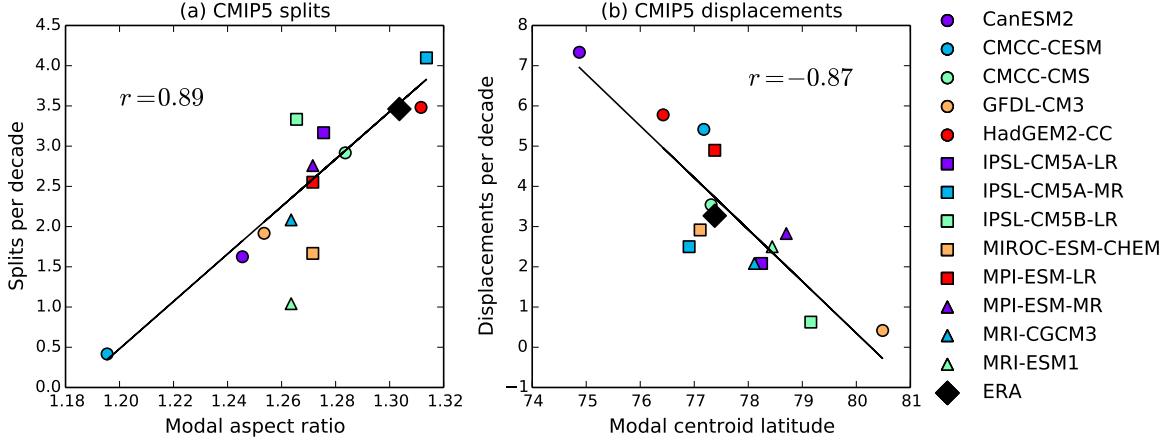

Figure 4.5: Comparison of the DJFM mean aspect ratio with frequency of split vortex events (a) and DJFM mean centroid latitude with frequency of displaced vortex events (b) in the CMIP5 ensemble and ERA. Linear best fits and the correlation coefficients for all the models are also shown.

implication of this is that the models are consistent in their representation of the variability of aspect ratio and centroid latitude, relative to the model climatology.

It can also be seen in Figure 4.5 that the values for ERA lie very close to the best fit lines of the CMIP5 models. This implies that the accuracy of a model's representation of the frequency of displaced and split vortex events can be significantly improved by a more accurate average undisturbed vortex state. Furthermore, while the ERA value for modal centroid latitude lies approximately in the middle of that for the CMIP5 models, only two models have a larger modal aspect ratio than ERA, indicating that a too circularly-symmetric vortex is a common bias among models.

The structure of the stratospheric polar vortex during split and displaced vortex events in the CMIP5 ensemble is shown in Figure 4.6. This displays composites of 10 hPa geopotential height at the onset date of the events for each model. It can be seen that the majority of models accurately reproduce splitting events as occurring along the 90°W–90°E axis, and displacement events with a vortex shifted towards Scandinavia and Siberia. CanESM2 is an exception to this, with split vortex events which are elliptical but centred quite far from the pole. The IPSL-CM5B-LR model also has a very different appearance of displaced vortex events, although this composite only consists of three events so differences

are unlikely to be statistically significant. There is also significant inter-model spread in the relative strengths of the Aleutian and Azores highs during split vortex events. Several models (GFDL-CM3, IPSL-CM5A-LR, IPSL-CM5B-LR, MRI-ESM1) show an approximately equal strength Aleutian and Azores highs, while others (CMCC-CMS, HadGEM2-CC, IPSL-CM5A-MR, MPI-ESM-LR, MPI-ESM-MR, MRI-CGCM2) show a weaker Azores high, which is in closer agreement with reanalysis. The more symmetrical Aleutian and Azores highs indicate a greater dominance of wave-2 activity in split vortex events than is found in observations, where not all split vortex events are dominated by wave-2 activity [Waugh, 1997; Mitchell *et al.*, 2013].

4.3 Stratosphere-troposphere coupling

4.3.1 Zonal-mean response to displaced and split vortex events

The time-height evolution of the atmosphere around split and displaced vortex events in each of the CMIP5 models is displayed in Figure 4.7. This shows composites of polar cap (60° - 90° N) geopotential height (Z) anomalies from 90 days before to 90 days following events. The anomalies are calculated from the climatology of each day for each model. The figures extend downwards only to 500 hPa (rather than 1000 hPa). This is because models differ in their representation of geopotential height which is below ground level; some allow negative values, while others set this as an undefined value. This introduces significant errors in the calculation of a climatology and anomalies at levels where the geopotential height is occasionally below ground level. Polar cap Z is highly correlated with the NAM (calculated from zonal mean Z according to the method of Baldwin and Thompson [2009]) over the levels shown in Figure 4.7. ? also demonstrated composites of the NAM and polar cap Z following SSWs to be very similar. Indeed, comparing Figures 4.7 (a) and (b) with Figure 3.10 shows that the ERA composites for polar cap Z and the NAM are very similar. In Figure 4.7 the number of events entering each composite is shown in the upper right-hand corner, and it should

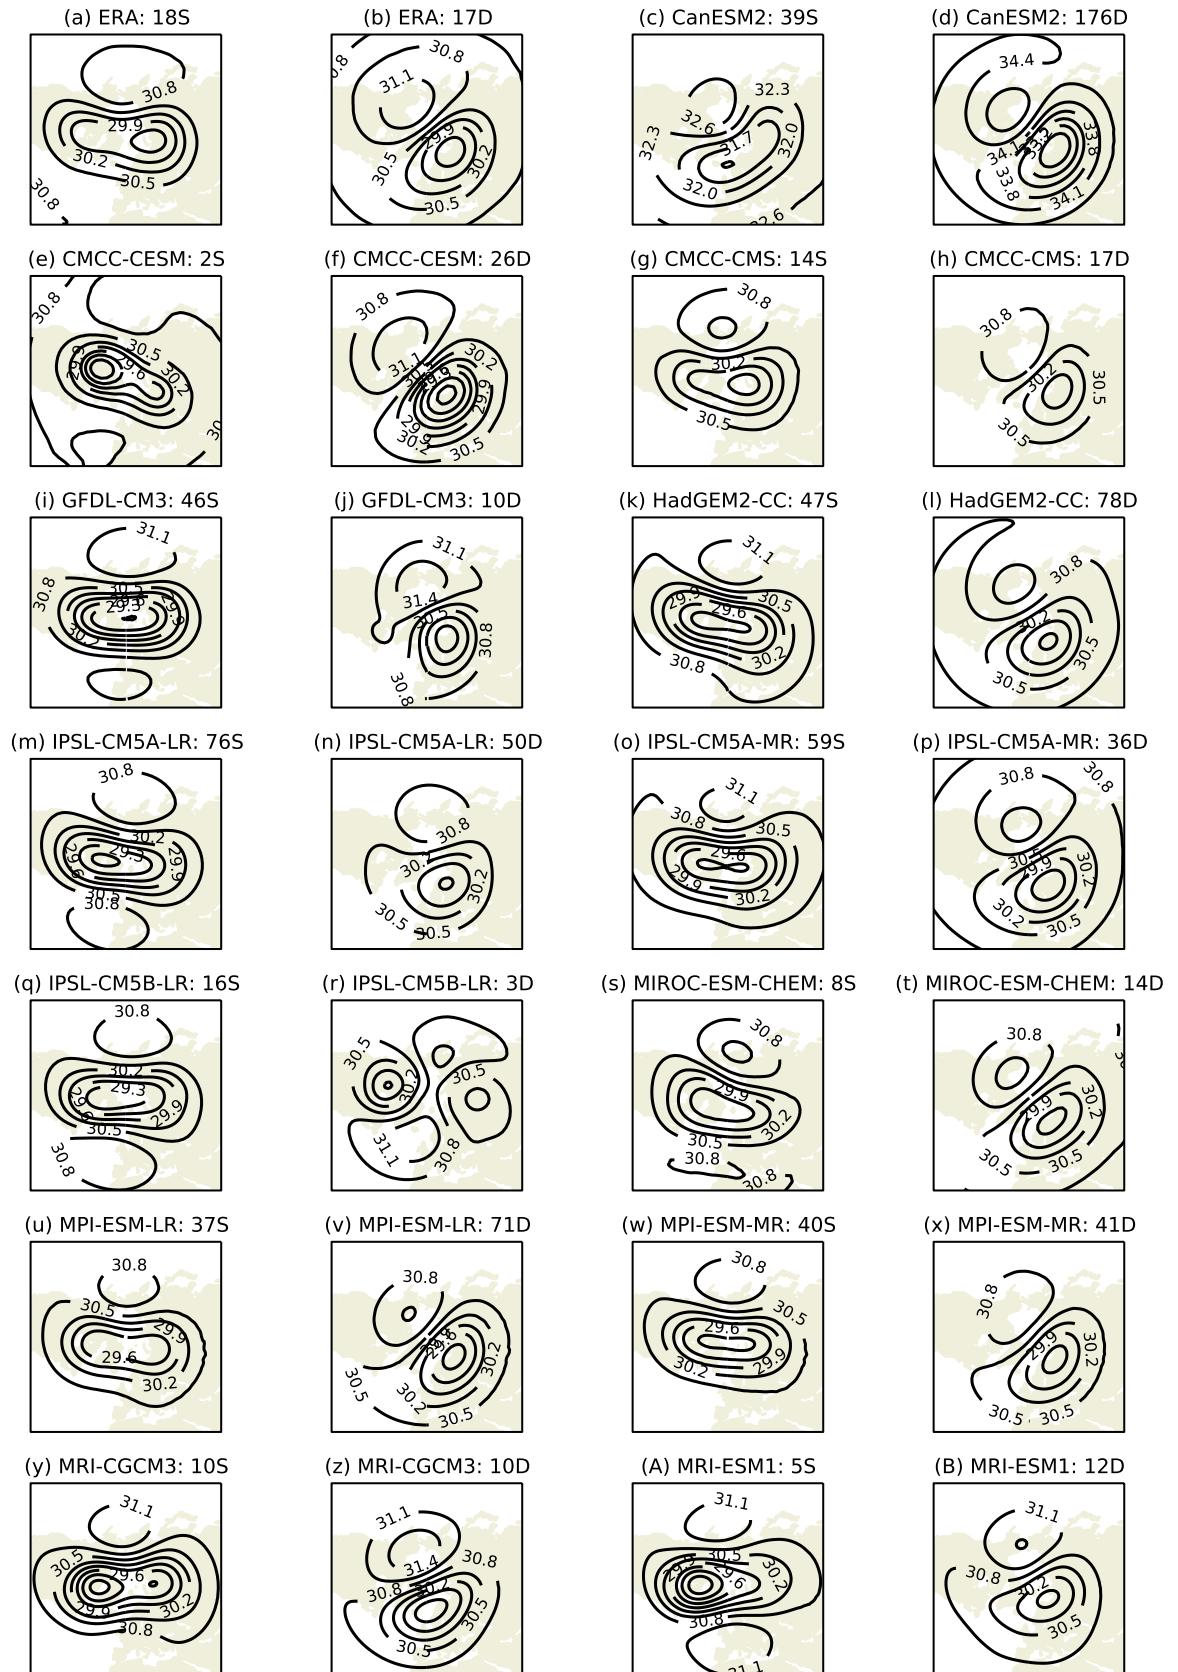

Figure 4.6: Composites of 10 hPa Z at the onset date of split (S) and displaced (D) vortex events in ERA (a,b) and the CMIP5 models. The number of events entering the composite and their type are shown in the title of each plot. The contour interval is 0.3 km.

be noted that composites of a small number of events are likely to be subject to significant statistical uncertainty.

It can be seen that there are large inter-model differences in the evolution of polar cap Z following split and displaced vortex events. For some models (e.g. CanESM2, CMCC-CMS) lower stratospheric anomalies persist for about 45 days, similar to reanalysis, while for others (e.g. IPSL-CM5A-LR, GFDL-CM3) these persist for much longer, beyond 60 days. There are also differences in the stratospheric precursors to events; while some models (e.g. CanESM2, GFDL-CM3, MRI-CGCM3) simulate a stronger negative anomaly prior to displacement events, similar to reanalysis, others (HadGEM2-CC, IPSL-CM5A-MR, MRI-ESM1), show more negative anomalies prior to split vortex events.

Most significantly, there is a large spread in the tropospheric anomalies over the 10-90 days following split and displaced vortex events. Several models (e.g. IPSL-CM5A-LR, IPSL-CM5A-MR, MPI-ESM-LR) show only very weak anomalies below approximately 200 hPa, while others (e.g., CMCC-CESM, GFDL-CM3, MRI-ESM1) show stronger anomalies. Among those models which do show stronger tropospheric anomalies, there are also differences in the relative magnitude following split and displaced vortex events. For instance, for GFDL-CM3, and MRI-ESM1 tropospheric anomalies following displaced vortex events are stronger, while for MIROC-ESM-CHEM and MPI-ESM-MR anomalies following split vortex events are stronger, in closer agreement with reanalysis.

As well as these large inter-model differences, there are also some consistent features among models. Almost all models show a barotropic onset to split vortex events, with anomalies occurring at the same time throughout the depth of the atmosphere. In contrast, displaced vortex events appear more baroclinic, with onset occurring first near the uppermost level. This is consistent with the difference found in reanalysis, indicating that this is likely to be a robust difference between the response to split and displaced vortex events. These features are also apparent in the multi-model mean (MMM) (Figures 4.7 C and D). This mean is calculated so as to give each event an equal weight (rather than each model), and so does not give undue weight to models with only a small number of events.

On the other hand this does mean that greater weight is given to models with more ensemble members and more events (almost one third of all displaced vortex events come from CanESM2), but the difference in baroclinicity of split and displaced vortex events is observed to be very consistent among models.

4.3.2 Spatial response to displaced and split vortex events

Mean sea-level pressure (MSLP) anomalies averaged over the 30 days following split and displaced vortex events for each of the CMIP5 models are displayed in Figure 4.8. Also shown are the anomalies for ERA (a,b) (the same as Figure 3.12) as well as the multi-model mean (c,d), again calculated so as to give each event an equal weight. The climatology from which anomalies are calculated is determined by a 10-day running mean of the average for each day of the year at each spatial location. The number of events entering each composite is shown, and again, care must be taken interpreting composites of a small number of events due to statistical uncertainty.

Following both split and displaced vortex events, all models show a positive MSLP anomaly near the North Pole, and a negative anomaly centred over Western Europe and the North Atlantic. This pattern is consistent with a negative projection onto the North Atlantic Oscillation. Less consistent among models are anomalies over the North Pacific; many models (e.g. MRI-CGCM3, IPSL-CM5A-LR) show positive anomalies, while MPI-ESM-LR and MPI-ESM-MR have negative anomalies following both split and displaced vortex events. MIROC-ESM-CHEM has different sign anomalies in the North Pacific following split (negative) and displaced (positive) vortex events. In the multi-model mean, a weakly positive North Pacific anomaly is seen.

Figure 4.9 illustrates that this difference in consistency of the Atlantic and Pacific MSLP anomalies also exists in the multi-model ensemble of all events. It shows the distribution of MSLP anomalies averaged 30 days following all modelled split and displaced vortex events at the approximate centres of action of the NAO (over the Azores at 38°N , 26°) and the Pacific-North American (PNA) pattern (central North Pacific at 45°N , 165°W). The North Atlantic distribution is

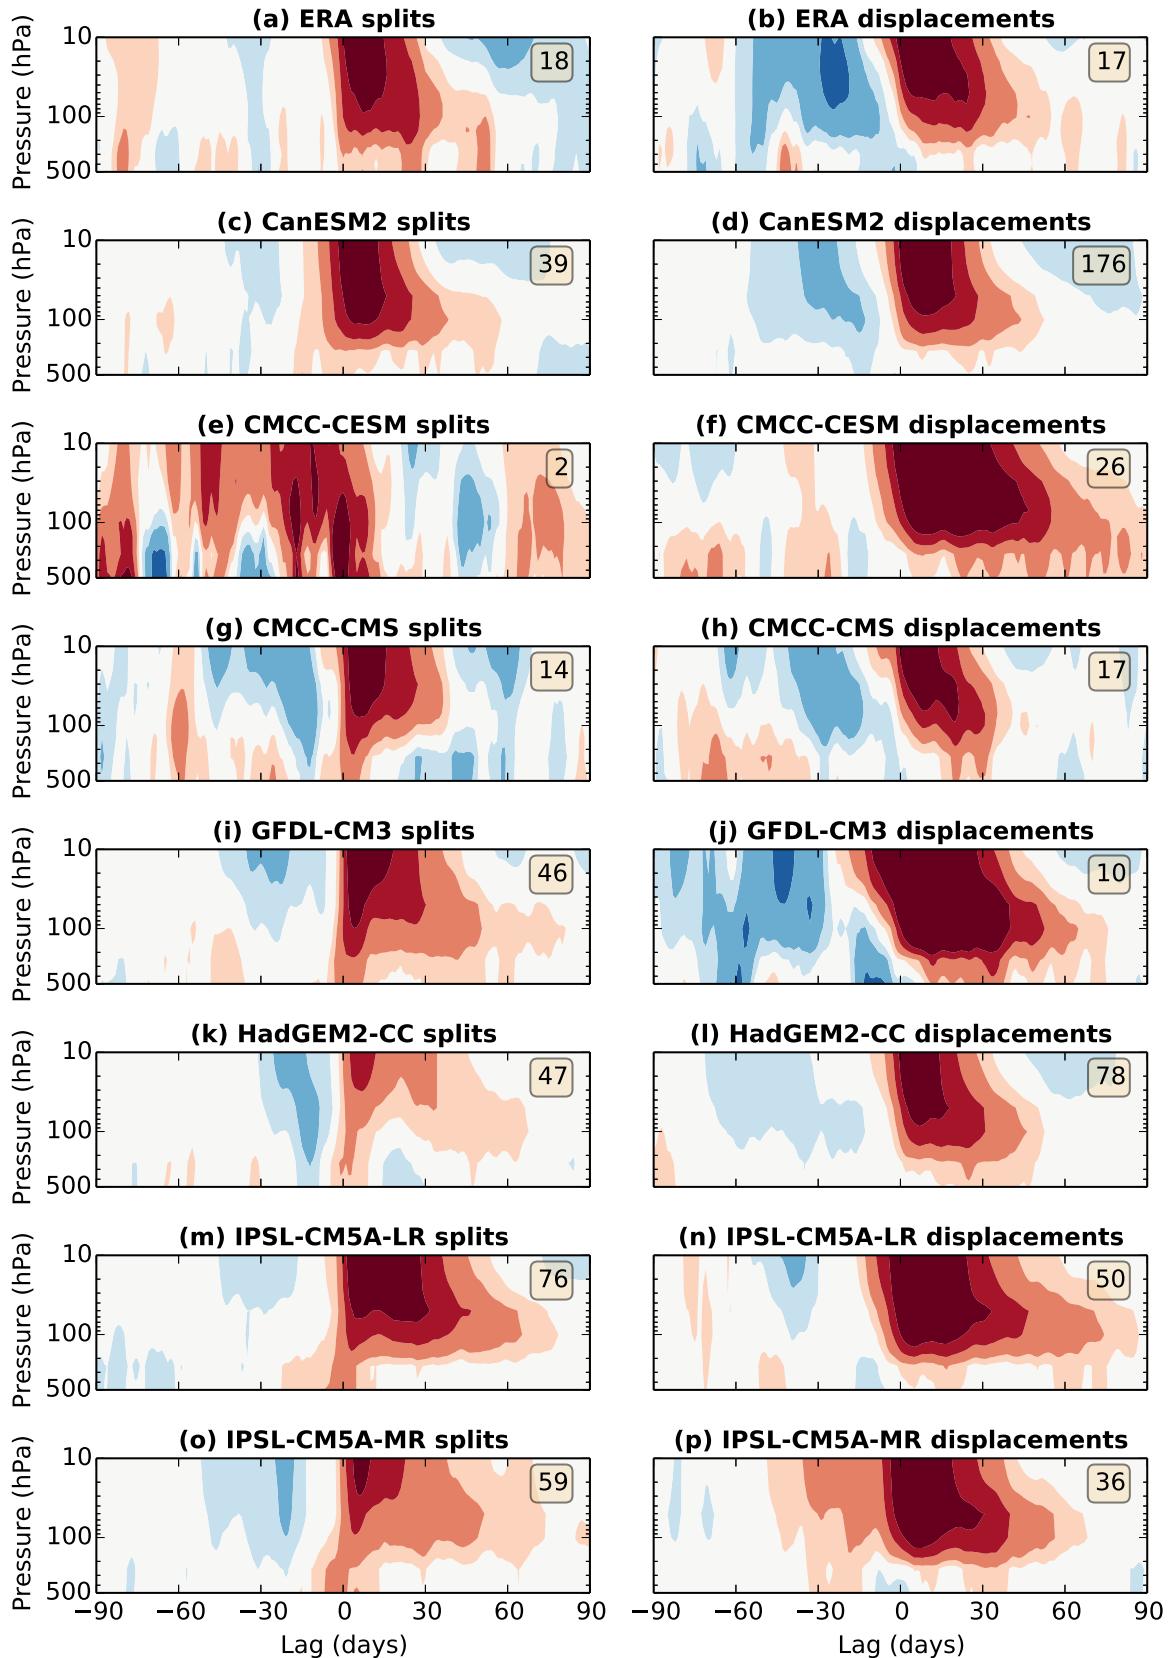

Figure 4.7: Composites of normalised polar cap averaged Z anomalies following split and displaced vortex events in ERA (a,b), the CMIP5 models, and the multi-model mean (C,D). Numbers in the upper right of each plot represent the number of events entering the composite.

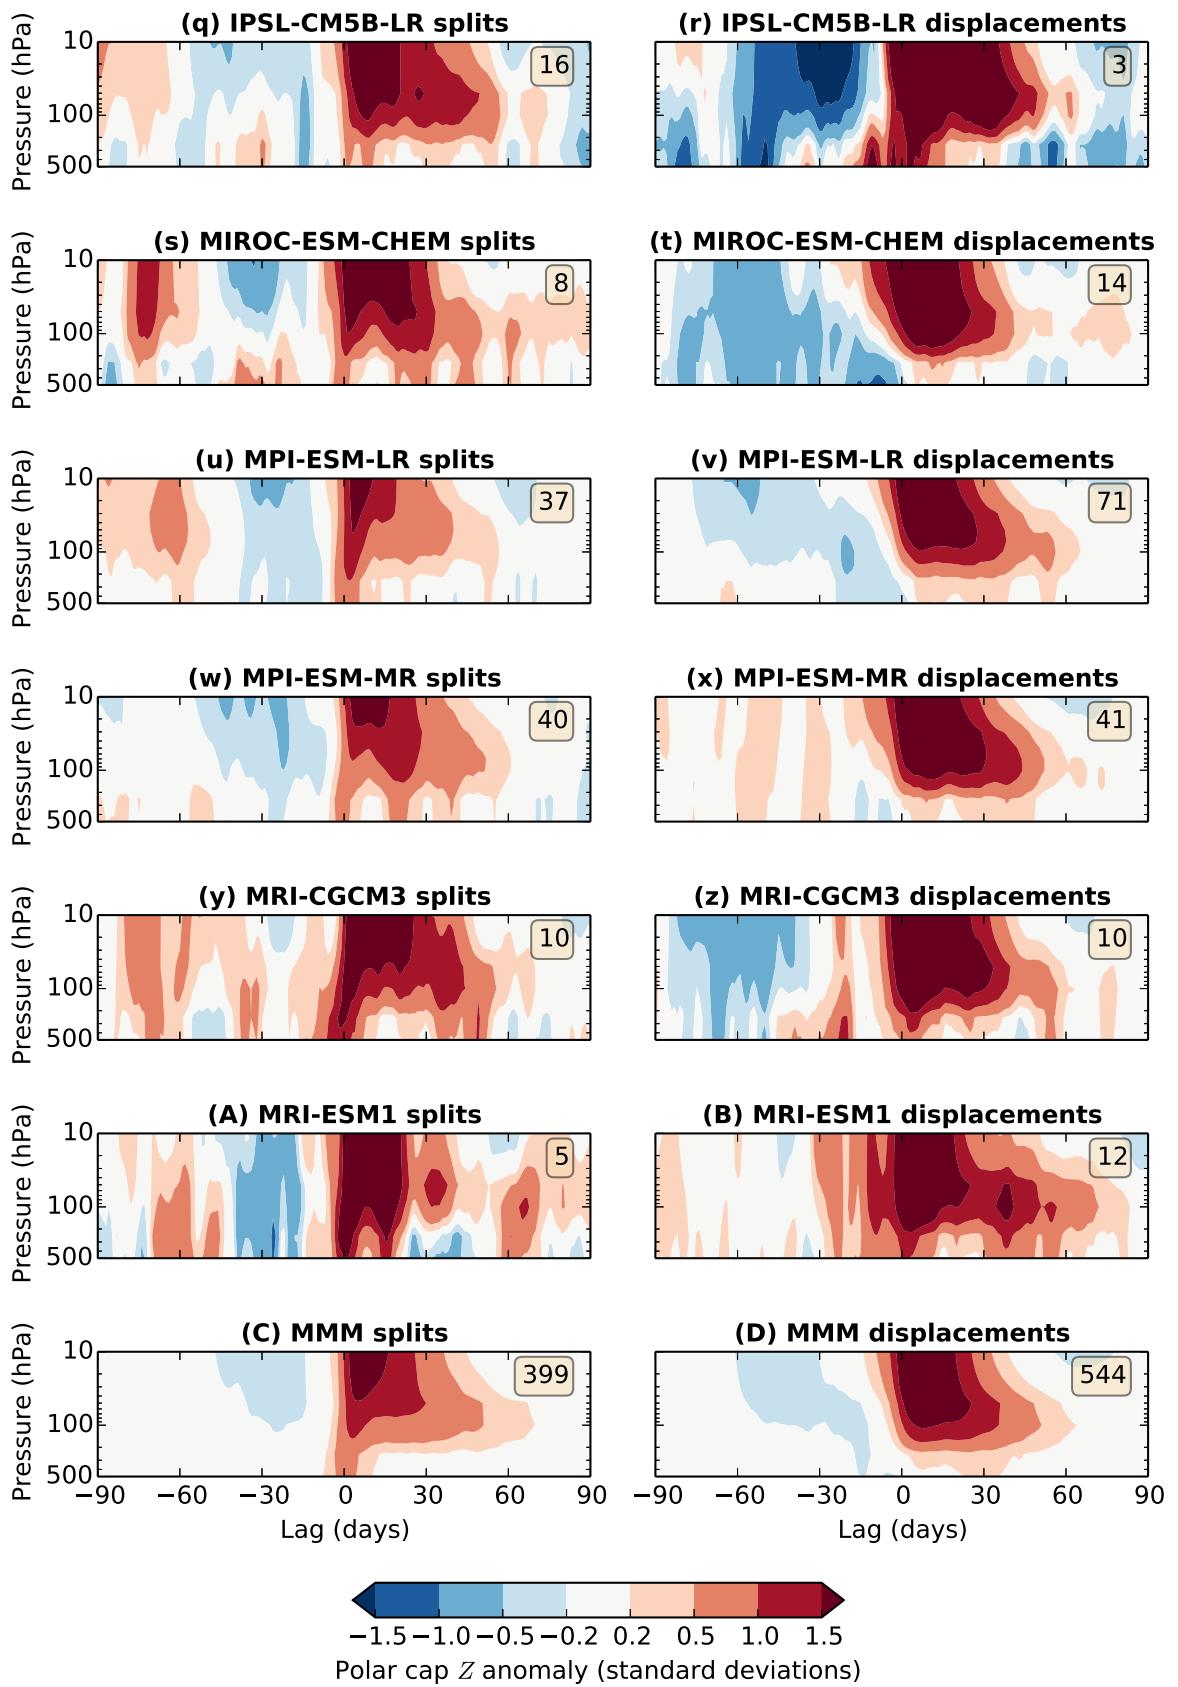

Figure 4.7: (Continued)

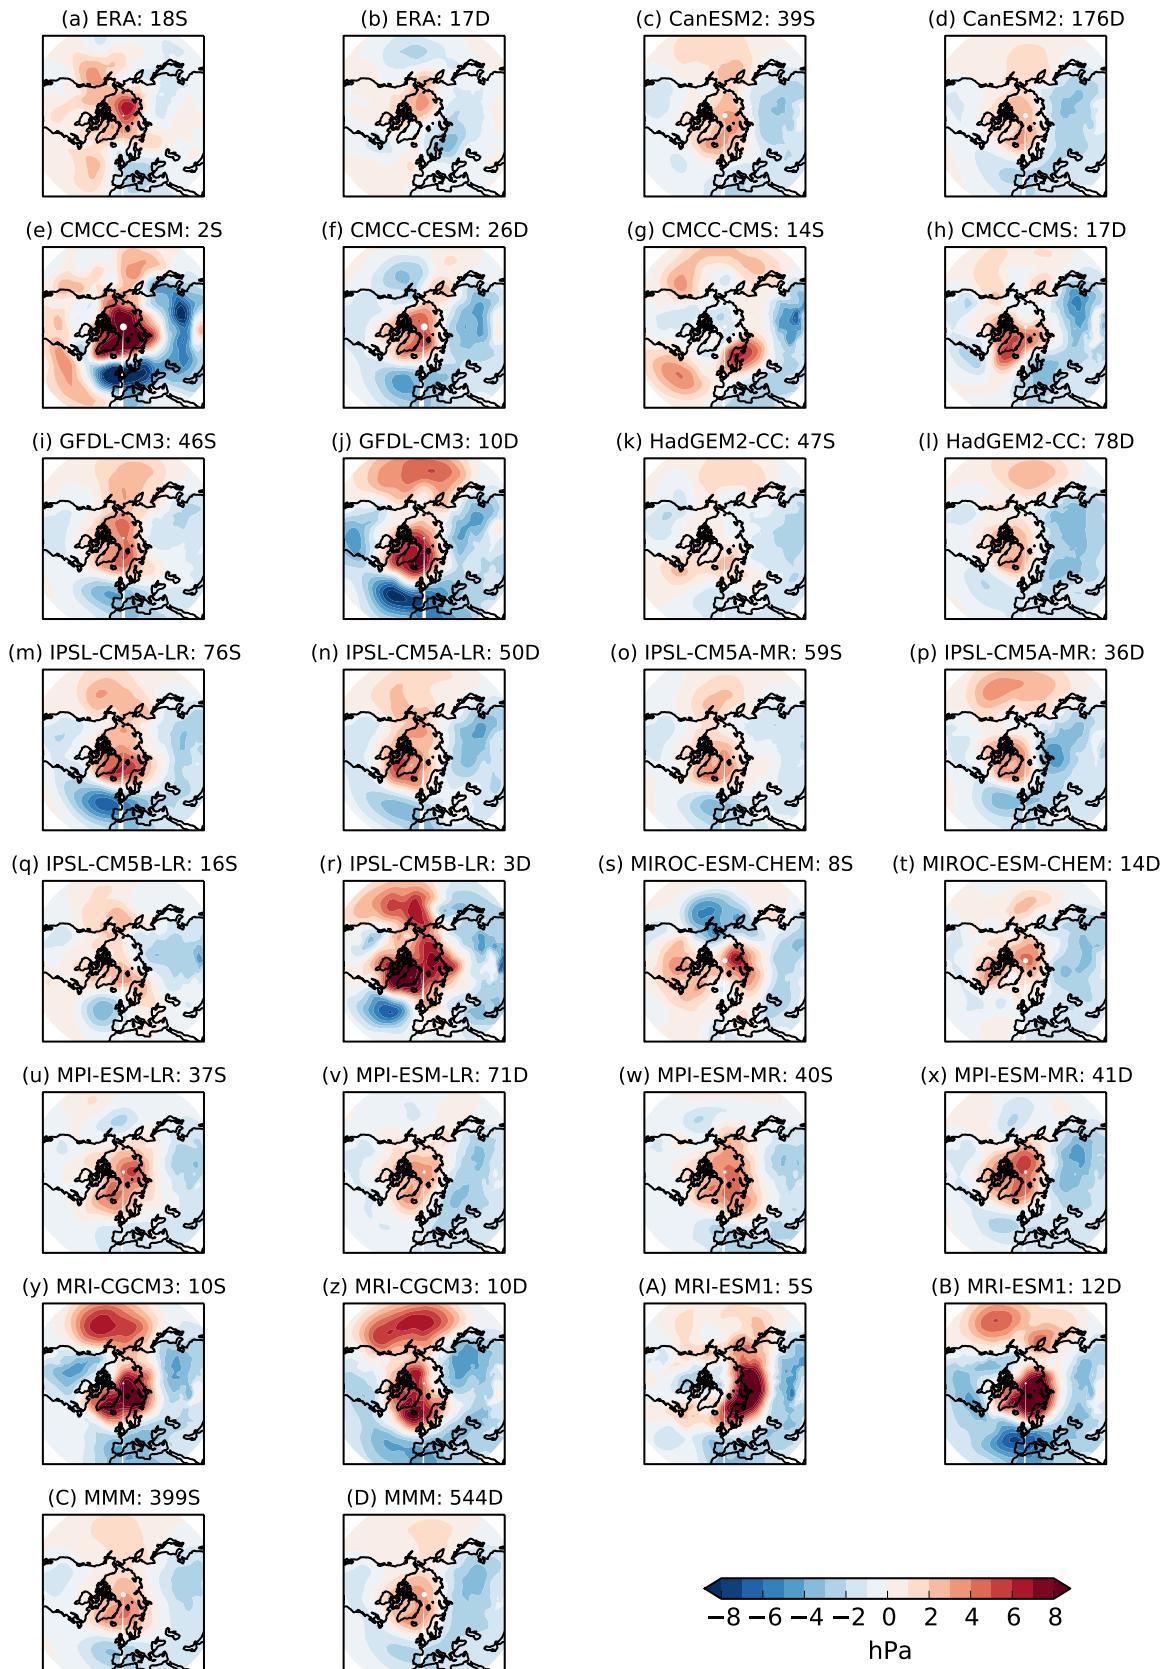

Figure 4.8: Composites of mean sea-level pressure anomalies averaged 0–30 days following split (S) and displaced (D) vortex events in the CMIP5 ensemble. Also shown are the ERA composite (a,b) and the multi-model mean (C,D). The multi-model mean is calculated as to give each event an equal weighting.

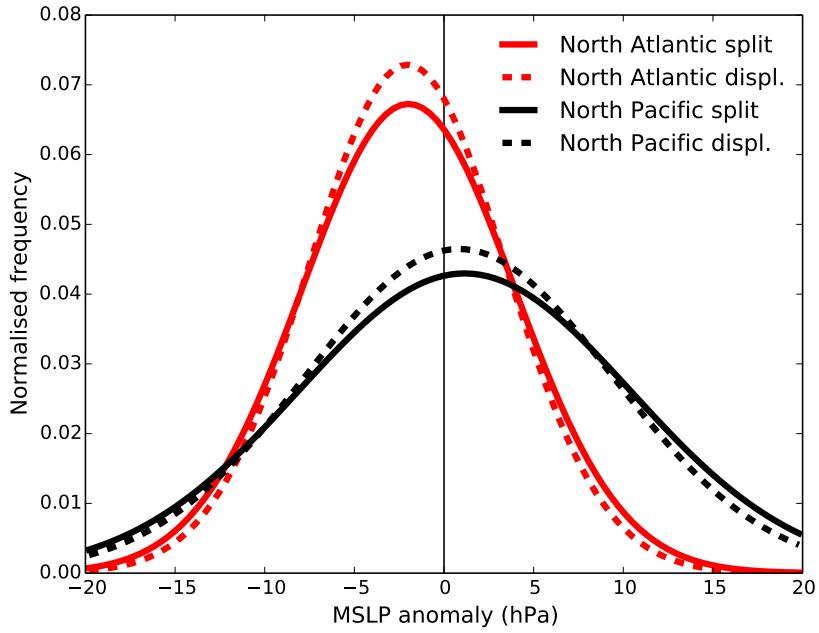

Figure 4.9: Distribution of mean sea-level pressure anomalies in the central North Atlantic ($38^{\circ}\text{N}, 26^{\circ}\text{W}$) and central North Pacific ($45^{\circ}\text{N}, 165^{\circ}\text{W}$) averaged over the 30 days following split and displacement events in all the CMIP5 models. These two locations correspond to centres of action of the NAO and PNA patterns respectively. Data are fitted with a Gaussian distribution.

centred further from zero and has a lower variance than the North Pacific distribution for both split and displaced vortex events. This is despite the fact that the standard deviation in monthly winter MSLP is approximately equal in the two regions [Allan and Ansell, 2006], and so again indicates the more consistent North Atlantic response.

This inconsistency in the Pacific anomalies has important consequences for the interpretation of zonal mean anomalies following split and displaced vortex events. For instance, the IPSL-CM5A-LR model shows weak tropospheric anomalies (relative to other models) of polar cap averaged Z following split and displaced vortex events (Figure 4.7 (m,n)), but a relatively strong NAO signal (Figure 4.8 (m,n)), particularly following split vortex events. The reason for this difference is that the model also shows relatively strong positive North Pacific anomalies, that to some extent cancel the North Atlantic anomalies in the polar cap average. Such an effect would also be seen in the NAM, even if calculated from non zonally-averaged Z , since the surface NAM pattern (the leading EOF

of MSLP) has centres of action of the same sign in the North Atlantic and North Pacific [e.g., *Ambaum et al.*, 2001].

A robust difference found between MSLP anomalies following split and displaced vortex events in almost all models and the multi-model mean is that anomalies over Russia and Eastern Europe are more strongly negative following displaced vortex events. In the multi-model mean, this difference has a magnitude of about 2-3 hPa across most of Russia. In order to understand the possible stratospheric influence on this difference, lower stratospheric anomalies are studied. Figure 4.10 shows composites of 100 hPa Z averaged over the 10 days following the onset of split and displaced vortex events. This shorter time period (rather than the 30 days used for the MSLP composites) is chosen to represent the typical time scale of a split or displacement of the vortex, which is shorter than the time scale taken for the re-formation of the vortex and return towards the climatological mean. However, it should be noted that composites taken over the 30 days show similar structure, but with reduced magnitude (not shown).

As well as the composite for each model, and the split minus displaced vortex difference, a multi-model mean is also shown in Figure 4.10 (Q,R,S). Because this is a mean of model absolute values, and models have different climatologies, the MMMs for split and displaced vortices are scaled to have the same hemispheric mean magnitude. This avoids introducing a bias in the climatology of any particular model into the MMM difference.

For all models with the exception of CanESM2, the 100 hPa Z split vortex composite shows an elliptical vortex with the major axis aligned along the 90°W-90°E line which is similar to the composite at 10 hPa (Figure 4.6). For the displaced vortex composite the 100 hPa vortex is centred over Siberia for almost all models, eastward of the 10 hPa composite which is centred over Scandinavia. This again highlights the more barotropic nature of split vortex events compared to baroclinic displaced vortex events, in which the vortex shows a westward tilt with height (as also demonstrated by *Matthewman et al.* [2009]).

In the split minus displaced vortex difference, the majority of models show a large positive region over Russia and Eastern Europe and a negative region

centred over northern Canada. The positive region over Siberia has a minimum, which is negative in some cases, located near 90°E, which is consistent with the position of minimum in the split vortex composite. It can be seen that the multi-model mean difference (Figure 4.10 (S)) is remarkably similar to the reanalysis difference (Figure 4.10), both in terms of the location and magnitude of anomalies. This suggests that the CMIP5 models, on average, realistically represent the evolution of split and displaced vortex events through the depth of the stratosphere. Again, this result is consistent among the majority of models, and so not highly sensitive to the exclusion or inclusion of any particular model.

Figure 4.11 shows the split minus displaced vortex composite difference for MSLP averaged 0-30 days following onset and the 100 hPa Z composite difference averaged 0-10 days following onset, for both ERA and the CMIP5 MMM. Statistical significance in the MSLP difference is calculated by a two-tailed bootstrap test with the null hypothesis that the anomalies following split and displaced vortex events are populations from the same probability distribution. The following procedure is used:

1. All events are grouped together and selected from them, with replacement, are two random subsets which are equal in size to the total number of split and displaced vortex events respectively.
2. The difference of the averages of these two subsets is taken.
3. The above is repeated 5000 times to form a distribution of random composite differences.
4. If the actual composite difference lies lower than the 2.5% or higher than the 97.5% levels of this distribution then it can be said there is a less than 95% chance that an anomaly at least this large would arise if anomalies following split and displaced vortex events are populations from the same distribution. Hence the null hypothesis can be rejected.

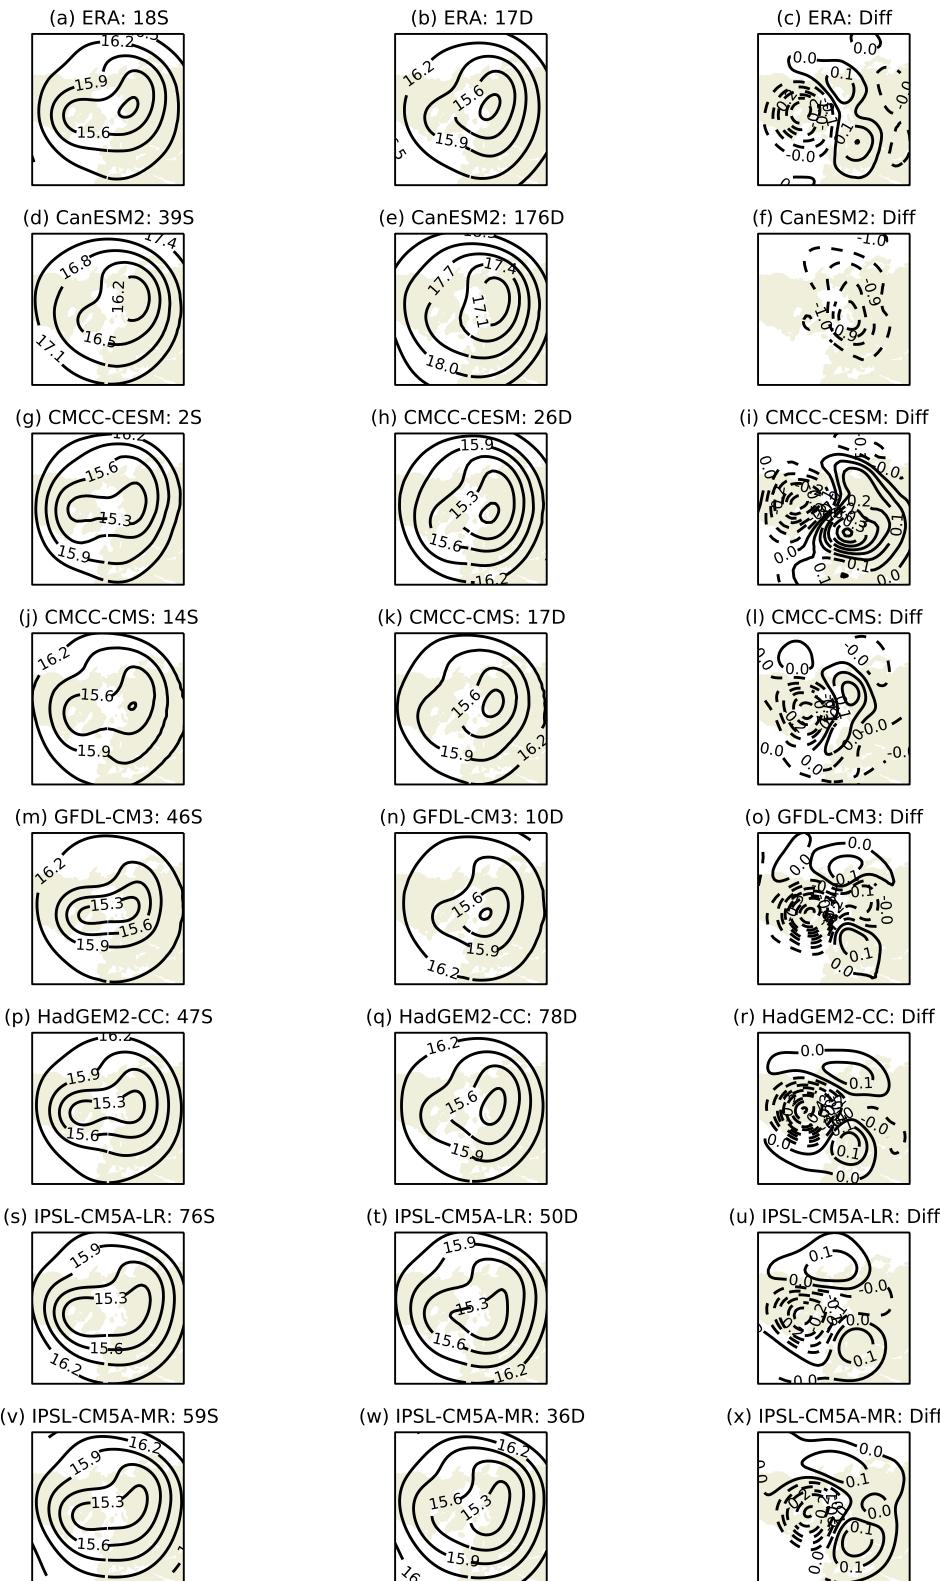

Figure 4.10: Composites of 100 hPa geopotential height (km) averaged in the 10 days following the onset of split (S) and displaced (D) vortex events in ERA, each of the CMIP5 models, and the multi-model mean (MMM). The right hand column displays the difference of splits minus displacements. The multi-model mean is calculated so as to give each event an equal weighting.

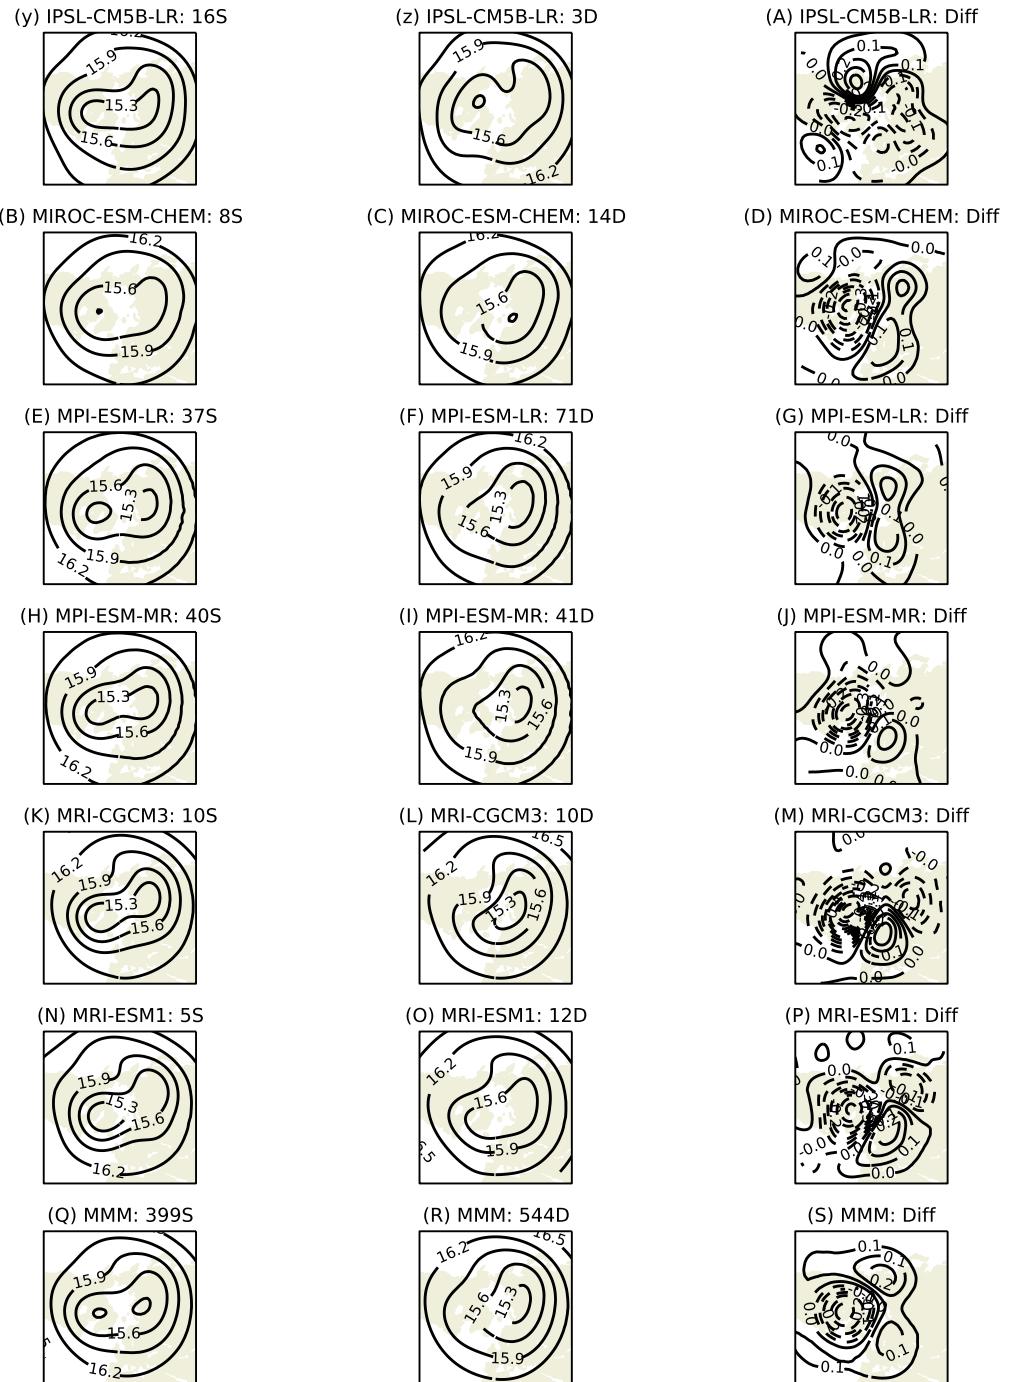

Figure 4.10: (Continued)

For the case of ERA, very little statistical significance in the composite difference is seen, while in the CMIP5 MMM there are large statistically significant regions. This is due to the greatly increased sample size in CMIP5; a total of 943 events compared to just 35 in ERA.

In the CMIP5 MMM difference the largest feature is the large positive anomaly (a result of a more negative anomaly following displaced vortex events) over Scandinavia, Eastern Europe and Russia. There is also a significant negative anomaly over northern Canada and a positive anomaly in the western Atlantic. This pattern is zonally asymmetric and so does not project strongly onto the polar cap average, therefore explaining the small difference in polar cap averaged Z (Figure 4.7 (C,D)). The CMIP5 difference pattern also does not strongly project onto the NAO as there is a similarly negative NAO following both split and displaced vortex events (Figure 4.8 (C,D)). For the ERA MSLP difference there are stronger negative anomalies over Europe (although not statistically significant) and positive anomalies over the North Pole, which does project more strongly onto the NAO, as discussed in Section 3.4.

The CMIP5 difference of Figure 4.11 shows the positive 100 hPa Z anomalies over Siberia over-lie the positive MSLP anomalies, while the negative 100 hPa Z over northern Canada over-lies negative MSLP anomalies. A somewhat similar, but not statistically significant pattern is seen in ERA, although the Siberian anomaly is more polewards and the negative anomaly over Canada is much weaker. Importantly, the 100 hPa pressure surface lies close to the tropopause, and 100 hPa Z can therefore give an indication of tropopause height. Indeed, comparing the 100 hPa Z and tropopause height anomalies for ERA (Figures 4.10 (a,b) and 3.13 (c,d)) shows that anomalous negative Z is approximately co-located with an anomalously high tropopause, although the tropopause height field is much noisier.

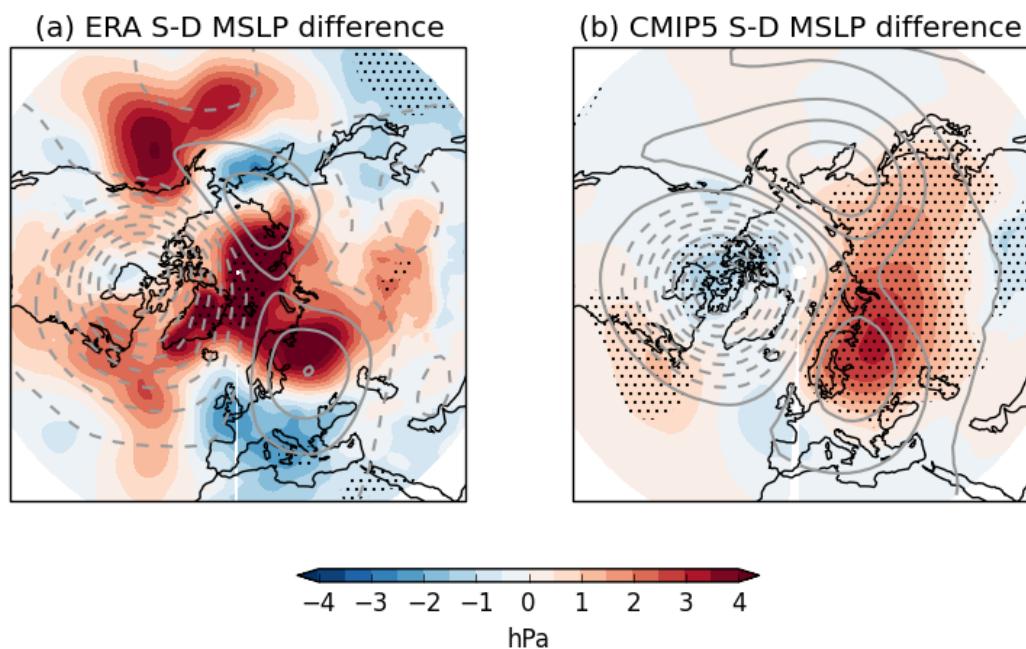

Figure 4.11: Difference (S-D) of composites of mean sea-level pressure averaged 0-30 days following split (S) and displaced (D) vortex events in ERA and the CMIP5 ensemble. Stippling indicates regions that are $>95\%$ significant according to a two-tailed bootstrap test. Grey contours represent the difference in 100 hPa geopotential height averaged 0-10 days following events the contour interval is 40 m, dashed contours represent negative values and the lowest magnitude contours are ± 20 m.

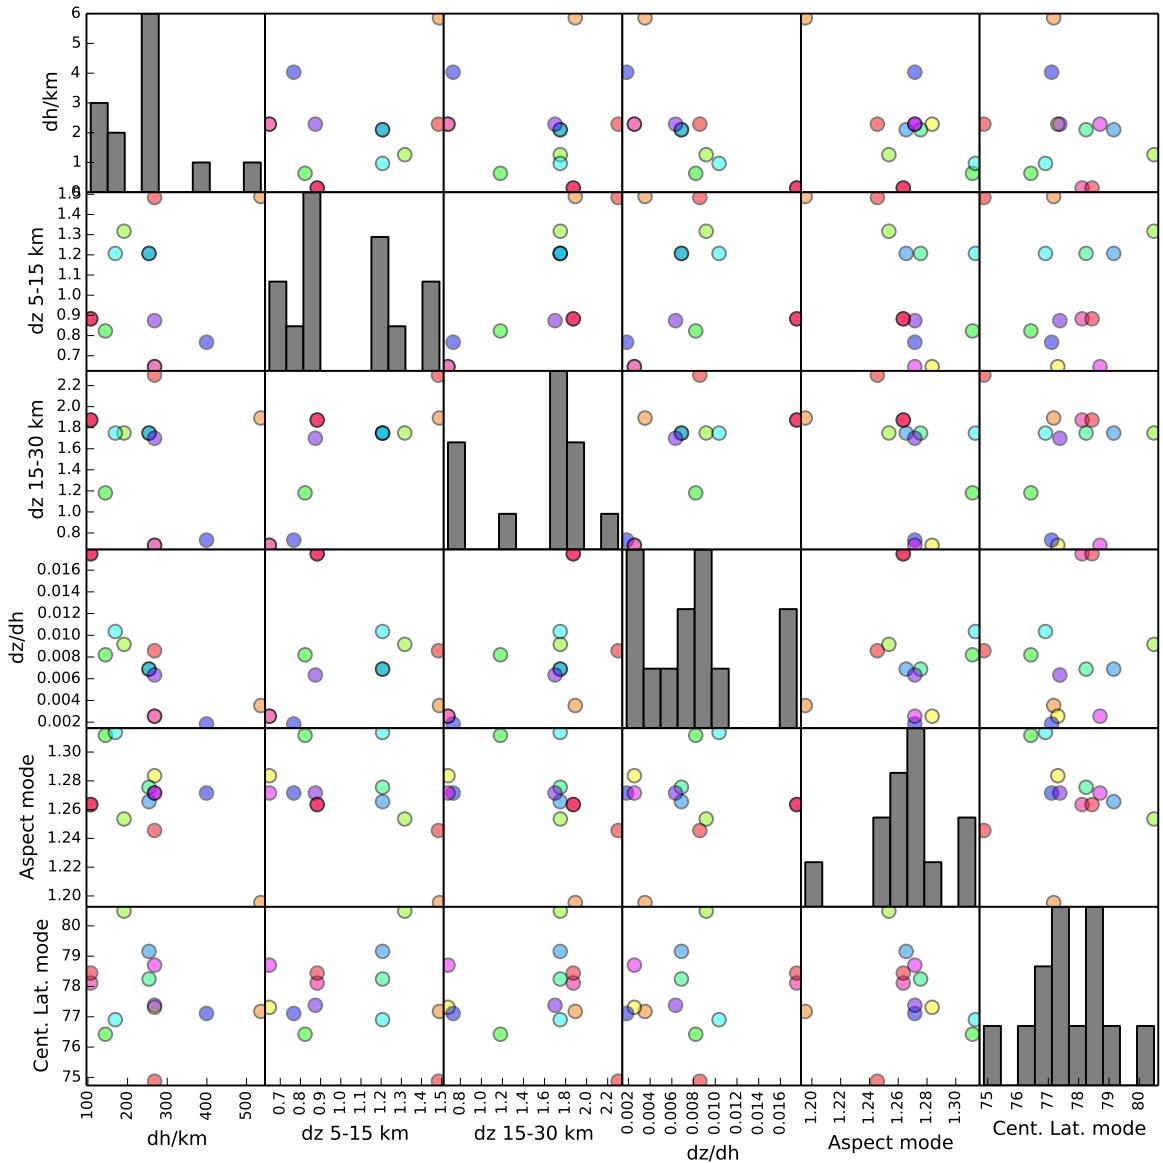

Figure 4.12: Relationship between model resolution, moment diagnostics, and stratosphere-troposphere coupling in the CMIP5 models. Model resolution is shown as horizontal resolution (dh), vertical resolution (dz) over 5-15 km and 15-30 km, and aspect ratio ($dz(5-15 \text{ km})/dh$). Histograms for the relevant quantities are shown along the leading diagonal.

4.4 Discussion

4.4.1 Effect of model resolution

We have demonstrated that there are large differences in the representation of the average undisturbed state of the stratospheric polar vortex among high-top CMIP5 models. This amounts to an inter-model range in the modal centroid latitude of more than 5° and in the aspect ratio of 0.12, which corresponds to (77% and 22% of the ERA standard deviation respectively). Because a similar number of models have a poleward as an equatorward centroid latitude bias, the multi-model mean is approximately accurate. In contrast, only two of 14 models have higher modal aspect ratio than reanalysis.

Importantly, we have shown that these biases in the undisturbed state of the vortex are closely related to biases in the frequency of split and displaced vortex events. As a corollary, models therefore have a realistic representation of variability relative to the average state. In order to understand the origin of these biases we now consider whether any of the model horizontal and vertical resolution properties listed in Table 4.1 are related to models' polar vortex climatology. Figure 4.12 shows the correlations between model resolution and modal aspect ratio and centroid latitude.

There are no statistically significant correlations between the modal aspect ratio or centroid latitude and horizontal resolution or between the centroid latitude and vertical resolution. However, a stronger relationship is found between vertical resolution and the modal aspect ratio and this is shown in more detail in Figure 4.13. The relatively wide scatter of points as well as the small correlation coefficient values indicate that vertical resolution fails to account for a substantial fraction of inter-model variability in the modal aspect ratio. However, the p -values shown indicate a relatively high level of statistical significance for both correlations. It should be noted that these correlations are not highly influenced by outliers. This can be seen by the bootstrap test p -values, as well as the rank correlations which are -0.60 (96.9%) and -0.75 (99.7%) for vertical resolutions over 5-15 km and 15-30 km respectively.

The two measures of vertical resolution, dz (5-15 km) and dz (15-30 km), are themselves correlated (see Figure 4.12), so it is difficult to interpret which region (if any) has the largest impact on the modal aspect ratio. It is interesting to note, however, that *Anstey et al.* [2013] found vertical resolution among CMIP5 models to correlate with increased NH winter blocking frequency. They found the strongest relationship to be with upper-troposphere/lower-stratosphere (UTLS) vertical resolution, which is where we find the strongest correlation with modal aspect ratio (although slightly lower statistical significance; see Figure 4.13). Blocking events are known to be closely linked to stratospheric variability; they influence upwards wave propagation into the stratosphere [*Polvani and Waugh*, 2004; *Woollings et al.*, 2010], and may also be affected by downwards the propagation of stratospheric anomalies [*Tomassini et al.*, 2012; *Mitchell et al.*, 2013; *Vial et al.*, 2013]. Hence, the combination of the present study with *Anstey et al.* [2013] may suggest that UTLS vertical resolution is an important factor in the representation of stratosphere-troposphere coupling.

Two important caveats should be noted in interpreting these correlations. First, comparing pairs of models from the same family but with different resolutions does not show a correlation between vertical resolution and modal aspect ratio. In the present ensemble this comparison is limited to IPSL-CM5A-LR/IPSL-CM5A-MR and MPI-ESM-LR/MPI-ESM-MR. It can be seen from Figure 4.13(a) that the IPSL models have the same vertical resolution but different modal aspect ratios and the MPI models have different vertical resolutions but very similar modal aspect ratios. A similar effect is also seen in comparing vertical resolution and blocking frequency [*Anstey et al.*, 2013]. While this is a very limited comparison of only two pairs of models, it may suggest that it is in fact other model differences which may give rise to the correlations shown in Figure 4.13.

A second caveat is that interpreting this significance, it should be noted that six different relationships between model resolution parameters and moment diagnostics have been tested in Figure 4.12 (treating the measures of vertical resolution as a single parameter since they are highly correlated). Assuming these parameters to be independent (i.e. a binomial distribution), there is an approximately

4.4. DISCUSSION

26% chance of finding at least one 95% significant correlation among those tested if the data are sampled from an uncorrelated distribution.

On the other hand, there is some physical motivation for the importance of UTLS vertical resolution in the representation of stratosphere-troposphere coupling because of the sensitivity of planetary wave propagation to vertical gradients in this region. This sensitivity can be measured by the quasi-geostrophic refractive index, n_s [Matsuno, 1970], with planetary waves tending to propagate towards regions of high n_s and becoming evanescent in regions where $n_s < 0$. It is given by

$$n_s^2 = \frac{1}{a\bar{u}} \frac{\partial \bar{q}}{\partial \phi} - \frac{s^2}{a^2 \cos^2 \phi} - \frac{f^2}{4N^2 H^2}, \quad (4.4)$$

where N^2 is the static stability, H scale height, s wavenumber, and

$$\frac{\partial \bar{q}}{\partial \phi} = 2\Omega \cos \phi - \frac{\partial}{\partial \phi} \left[\frac{1}{a \cos \phi} \frac{\partial}{\partial \phi} (\bar{u} \cos \phi) \right] - \frac{a}{\rho_0} \frac{\partial}{\partial z} \left(\frac{\rho_0 f^2}{N^2} \frac{\partial \bar{u}}{\partial z} \right). \quad (4.5)$$

It is therefore apparent that n_s is sensitive both to the vertical gradient in static stability ($\partial N^2 / \partial z$) and the vertical shear of zonal wind ($\partial \bar{u} / \partial z$). Using a linear primitive equation numerical model, Chen and Robinson [1992] found a large vertical gradient in static stability near the tropopause as well as a strong vertical shear of the zonal flow. They found that small changes in these quantities have a large effect on n_s , and therefore that the tropopause acts as a “valve” for the propagation of planetary waves between the troposphere and stratosphere. In a more recent observational study, Grise et al. [2010] have confirmed the existence of fine-scale structure in static stability near the tropopause. It therefore may be the case that a higher model vertical resolution near the tropopause is necessary to capture this structure and hence more accurately represent planetary wave propagation from troposphere to stratosphere.

The fact that there is not a significant relationship between the modal centroid latitude and vertical resolution may suggest that wave-2 propagation is more sensitive to vertical resolution than wave-1. This is because aspect ratio is highly correlated with wave-2 activity and centroid latitude with wave-1 [Waugh and Randel, 1999]. It might be expected that wave-2 propagation is more sensitive to near-tropopause resolution because the ‘window’ for permissible wave-2 propagation

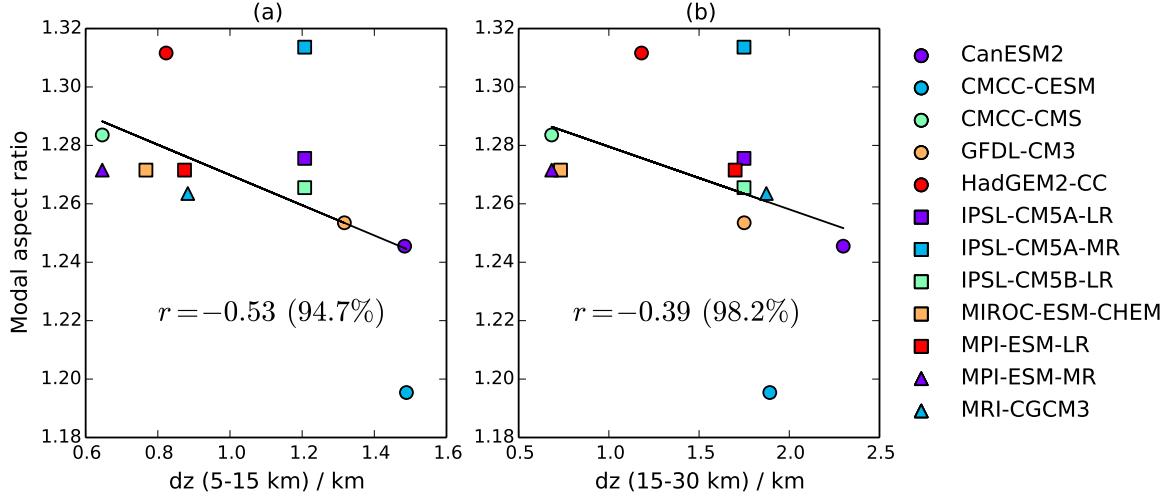

Figure 4.13: Expansion from Figure 4.12 of the correlation between modal aspect ratio and model vertical resolution over two regions (5-15 km and 15-30 km). Correlations, r , are shown along with the p -value calculated by a bootstrap test with null hypothesis $r = 0$.

is narrower (*Charney and Drazin* [1961]; Equation ??). Hence smaller differences in vertical gradients are required to exclude wave-2 propagation than wave-1 propagation.

Overall, a more systematic study is necessary to understand the importance of UTLS vertical resolution in the representation of stratosphere-troposphere coupling by climate models. This should consist of a ‘clean comparison’ of models in which only vertical resolution is varied, and which therefore avoids the difficulty of interpreting results when many parameters are varied at once as in the CMIP5 ensemble.

4.4.2 Measures of stratosphere-troposphere coupling

We have shown that zonally-averaged quantities such as polar cap Z (which is highly correlated with the NAM [?]) following split and displaced vortex events are much less consistent among models than the NAO. This inconsistency is dominated by differences in the North Pacific, with some models showing positive MSLP anomalies and others negative. Interestingly, a similar result was found in the recent study of *Davini et al.* [2014], who found the blocking pattern associated with SSWs to be consistent with that associated with the NAM over the North

4.4. DISCUSSION

Atlantic, but not over the North Pacific.

Following *Baldwin and Dunkerton* [2001], many studies of stratosphere-troposphere coupling have focused on the lag-height behaviour the NAM. For instance the comparison of stratosphere-troposphere coupling in high-top and low-top CMIP5 models by *Charlton-Perez et al.* [2013]. This and several other studies make further approximations as to the zonal nature of the coupling by calculating the NAM based on zonal-mean geopotential height, according to the method of *Baldwin and Thompson* [2009]. Our results suggest that because of the difference in model consistency over the two ocean basins, zonal-mean diagnostics or the NAM alone are not a good descriptors of inter-model variability. Therefore, we suggest that the NAO index or the full two-dimensional surface fields should be shown alongside the NAM when making inter-model comparisons.

This difference between the NAM and NAO signals in CMIP5 models may also give some insight into the physical relevance of these two modes of variability. Some studies have suggested that the NAO is in fact a regional manifestation of the planetary-scale annular structure of the NAM [e.g., *Thompson and Wallace*, 1998; *Wallace and Thompson*, 2002]. Furthermore, many observational studies have asserted that tropospheric anomalies following SSWs represent the NAM [e.g., *Baldwin and Dunkerton*, 1999, 2001; *Thompson et al.*, 2000].

On the other hand, *Amбаум et al.* [2001] suggested that the NAO paradigm is a more physically relevant measure of NH variability than the NAM. They found that MSLP anomalies over the North Atlantic and Pacific are not significantly correlated and argued that that the annular NAM pattern is a statistical artifact. *Huth* [2006] also showed that principal component analysis favours the NAO as the more physically relevant mode of variability. Furthermore, *Amбаум and Hoskins* [2002] found that changes in North Pacific tropospheric subtropical and polar jets are much less correlated with the strength of the stratospheric polar vortex than are the North Atlantic jets.

Under the significant assumption that the CMIP5 models can accurately represent the physics underlying these modes of variability, our results tend to favour

the NAO rather than the NAM as the more physically relevant mode, at least in terms of stratosphere-troposphere coupling.

4.4.3 Difference between split and displaced vortex events

As well as the consistent NAO signal following split and displaced vortex events, we have found that there are also some consistent differences in anomalies following the two types of event. In particular, MSLP anomalies following displaced vortex events are more negative over Scandinavia and Siberia than following split vortex events. From the fact that these MSLP differences are co-located with 100 hPa Z (Figure 4.11), which is in turn related to tropopause height, it may be possible to gain some understanding of the mechanism behind the difference in the surface response to split and displaced vortex events.

This co-location of surface anomalies and tropopause height is consistent with a localised spinup/spindown caused by stretching/compression of the tropospheric column. Changes in tropopause height are, in turn, caused by the bending of isentropic surfaces towards PV anomalies resulting from the movement of the stratospheric polar vortex. Such a mechanism was discussed by *Hartley et al.* [1998], *Ambaum and Hoskins* [2002], *Black* [2002], and in Section 2.4.3.

Other mechanisms that have been proposed for stratosphere-troposphere coupling fail to account for these regional differences. For instance, the amplification of intrinsic modes of variability [*Robinson*, 1991] can only explain differences which project onto these modes such as the NAO or NAM, unlike observed difference. Stratosphere-troposphere coupling by the reflection of planetary waves [*Perlitz and Harnick*, 2003; *Shaw et al.*, 2010] also cannot explain the observed difference since it does not project onto the dominant tropospheric planetary wave modes.

This argument relates only to the mechanism underlying the *difference* between the surface responses to split and displaced vortex events, and not to the overall responses. It is important to note that there are many similarities in the responses, especially in the NAO region. All the mechanisms discussed in Section ?? can be used to explain a stratospheric influence on the NAO, and since they are not

physically inconsistent with one another, it is possible that a number may operate at the same time.

Unfortunately, the small number of observed split and displaced vortex events combined with large tropospheric noise means there is very little statistical significance in the observed difference of MSLP anomalies (see Figure 4.11(a)). Hence it is not possible to compare our model and observational results for this difference, and there remains the possibility that CMIP5 models do not realistically represent the surface responses to split and displaced vortex events. Therefore, it is possible that stratosphere-troposphere coupling mechanisms in models are different to those in the real world.

4.5 Conclusions

Applying the method developed in Chapter 3, the climatology of the stratospheric polar vortex and its coupling with the troposphere has been analysed in stratosphere-resolving CMIP5 simulations. Returning to the three main objectives of this chapter (Section 4.1), the following conclusions have been reached:

- 1. How do models represent the stratospheric polar vortex and stratosphere-troposphere coupling?**

A wide range of biases among CMIP5 models has been found in the average state of the stratospheric polar vortex. Some models have a vortex which is too equatorward, while others too poleward. The majority of models have a vortex which is too circularly symmetric. These biases have been shown to relate closely to biases in the frequency of split and displaced vortex events. In the multi-model mean, however, the frequency of these events is in agreement with observations.

Almost all models accurately simulate the more barotropic nature of split vortex events compared to displaced vortex events. MSLP anomalies following these events consistently show a negative NAO in line with observations, but are much less consistent in the North Pacific, leading to a large spread when zonal mean quantities are investigated.

2. Is model resolution related to vortex variability?

There is a statistically significant correlation between near-tropopause vertical resolution and modal aspect ratio among models. However, this relationship is not seen among the two pairs of models from the same family. On the other hand, the tropopause region is known to be important for the propagation of planetary waves due to high vertical gradients of zonal wind shear and static stability. This may be suggestive of the need for high vertical resolution to accurately simulate stratospheric planetary wave activity and hence vortex aspect ratio. No relationships have been found between horizontal resolution and vortex variability.

3. Can models be used to understand mechanisms behind stratosphere-troposphere coupling?

Consistent differences in the MSLP anomalies following split and displaced vortex events in the CMIP5 models have been found to be co-located with the difference in near-tropopause Z anomalies. This is consistent with a localised tropospheric response to stretching or compression of the tropospheric column being the mechanism behind the different responses to the two events. It also excludes mechanisms which rely on projections onto major modes of variability such as the NAO or NAM. This result only applies to the difference between responses to split and displaced vortex events, not the individual responses, which share many similarities.

CHAPTER 5

The role of the stratosphere in seasonal prediction

Most of work in this chapter which relates to the Southern Hemisphere was published in *Journal of Climate* [?].

5.1 Introduction

Accurate prediction of the atmospheric circulation several months in advance relies on the presence of low-frequency predictable signals in the climate system. It has now been demonstrated that the stratosphere is an important pathway for the communication of predictable tropical signals across the globe; in particular, the El Niño-Southern Oscillation (ENSO) [Bell *et al.*, 2009; Ineson and Scaife, 2009; Hurwitz *et al.*, 2011], Quasi-Biennial Oscillation (QBO) [Marshall and Scaife, 2009; Garfinkel and Hartmann, 2011], and 11-year solar cycle [Haigh, 2003; Gray *et al.*, 2013]. These teleconnections allow for the possibility of significant predictability in regions remote from the direct effect of the signal. Despite this, many operational seasonal forecast models include only a poor representation of the stratosphere [Maycock *et al.*, 2011], and it has been suggested that this contributes to their lack of seasonal forecast skill in the extratropics [Smith *et al.*, 2012].

Furthermore, because stratospheric anomalies persist for longer than those in the troposphere and can influence surface weather patterns [e.g., Baldwin and

Dunkerton, 2001], the initial conditions of the stratosphere itself can act as a source of enhanced predictability [*Baldwin et al., 2003; Charlton et al., 2003; Christiansen, 2005; Hardiman et al., 2011*]. The effect of the stratosphere on the troposphere is especially pronounced following SSW events, and past work has focused on the influence of these events on forecast skill. For instance, both *Kuroda [2008]* and *Sigmond et al. [2013]* found that enhanced tropospheric predictability can be obtained if forecasts are initialised at the onset of SSW events. However, SSWs are highly nonlinear events which are not predictable beyond about two weeks in advance in current forecast systems [*Marshall and Scaife, 2010; Taguchi, 2014*], limiting their usefulness in seasonal prediction. SSWs also occur almost exclusively in the Northern Hemisphere (NH), with only one event in the approximately 60 year record having been observed in the Southern Hemisphere (SH), in September 2002 [*Roscoe et al., 2005*].

The rarity of SSWs in the SH is a result of less dynamical forcing from vertically propagating planetary waves in the SH relative to the NH stratosphere. This, in turn, comes about because of lesser SH orography and land-sea temperature contrasts which can excite planetary waves. This reduced variability also means that anomalies in the Antarctic stratosphere persist for longer than those in the Arctic [*Simpson et al., 2011*]. Hence, the SH stratospheric circulation may be predictable on longer time scales, and thus more useful for seasonal forecasts despite the lack of SSWs. Indeed, *Thompson et al. [2005]* and *Son et al. [2013]* have found that smaller-amplitude variations in the Antarctic stratospheric polar vortex are followed by coherent temperature and pressure anomalies at the Earth's surface which resemble the Southern Annular Mode (SAM) pattern. These observations led *Roff et al. [2011]* to find that improved forecasts of the SAM up to 30 days ahead may be achieved with a stratosphere-resolving model. The SAM is the dominant mode of variability of the extratropical Southern Hemisphere sea-level pressure and affects the position of storm tracks, rainfall, surface air temperature, and ocean temperatures across the extratropics [e.g., *Silvestri and Vera, 2003; Reason and Rouault, 2005; Hendon et al., 2007*]. As such, there are considerable societal benefits, and interests in its prediction [*Lim et al., 2013*].

5.1. INTRODUCTION

Another reason for interest in the prediction of the Antarctic stratosphere is the interannual variability in springtime ozone depletion, which can significantly affect the amount of harmful ultraviolet radiation reaching the Earth's surface over the Southern Hemisphere. The magnitude of this interannual variability is a significant fraction of the magnitude of long-term depletion caused by emission of chlorofluorocarbons (CFCs) and other ozone-depleting substances. While ozone-depleted air is confined over the polar region by the stratospheric polar vortex during winter and spring (resulting in the ozone hole), this air is released to mid-latitudes following the ultimate breakdown of the vortex (final warming) in late spring/early summer. The extent of the resulting summertime ozone depletion is largely determined by the total deficit in ozone over the Antarctic during spring [*Bodeker et al., 2005*].

Salby et al. [2012] have shown that interannual variations in Antarctic ozone depletion are highly correlated with changes in planetary wave forcing of the stratosphere. They found that the anomalous vertical Eliassen-Palm (EP) flux (a measure of meridional eddy heat flux) at 70 hPa poleward of 40°S during August–September explains almost all the interannual variance of anomalous ozone depletion during September–November. Using this relationship, they postulate that accurate prediction of planetary wave forcing could allow skillful seasonal forecasts of ozone depletion.

The influence of planetary wave forcing on ozone depletion comes about through both chemical and dynamical mechanisms. Planetary wave breaking causes an increase of the strength of the stratospheric residual mean meridional circulation [*Haynes et al., 1991*], with a resultant increase in large-scale descent and adiabatic warming over the pole. This warming inhibits the formation of polar stratospheric clouds which have a vital role in the activation of halogen species that cause the chemical depletion of ozone. The increased meridional circulation as well as an enhancement of horizontal two-way mixing caused by planetary wave breaking, also causes an increase in the dynamical transport of tropical ozone-rich air to the polar regions, further increasing ozone concentrations. Breaking planetary waves can also modify the geometry of the stratospheric

polar vortex, stripping away elements of ozone-depleted air [Waugh *et al.*, 1994], or in the extreme case of the 2002 SSW causing the ozone hole to split in two [Charlton *et al.*, 2005].

Here, we address directly the predictability of the stratospheric polar vortices using a set of historical hindcasts (or historical re-forecasts) from a new operational seasonal forecast system with a fully stratosphere-resolving general circulation model. The system accurately simulates the climatology of the NH stratospheric polar vortex including the aspect ratio and centroid latitude. However, we find it does not skilfully predict the winter mean vortex strength, the occurrence of SSWs, or split and displaced vortex events. On the other hand, we find significant skill in the prediction of the Antarctic stratospheric polar vortex up to four months in advance, including for the 2002 SSW. Using the observed relationship between column ozone quantities and the stratospheric circulation, we are then able to infer skillful predictions of springtime ozone depletion, confirming the hypothesis of Salby *et al.* [2012]. This exceeds the lead-time of other contemporary ozone forecasts, which are typically no more than two weeks [Eskes, 2005]. The forecast system also shows significant levels of skill in the prediction of the surface SAM at seasonal lead times. By studying the variation of hindcast skill with time and height, we demonstrate that this skill is significantly influenced by the descent of predictable stratospheric circulation anomalies.

5.2 Seasonal forecast system

The analysis in this chapter is based on results from a set of hindcast predictions produced by the Met Office Global Seasonal Forecast System 5 (GloSea5) [MacLachlan *et al.*, 2014]. This system is based upon the HadGEM3 coupled general circulation model [Hewitt *et al.*, 2011], with an atmospheric resolution of 0.83° longitude by 0.56° latitude, 85 quasi-horizontal atmospheric levels and an upper boundary at 85 km. The ocean resolution is 0.25° in longitude and latitude, with 75 quasi-horizontal levels.

5.2. SEASONAL FORECAST SYSTEM

Initial conditions for the atmosphere and land surface were taken from the ERA-Interim reanalysis [Dee *et al.*, 2011], and initial ocean and sea-ice concentrations from the GloSea5 Ocean and Sea Ice Analysis, based on the FOAM data assimilation system [Blockley *et al.*, 2013]. The ERA-Interim data are linearly interpolated onto model levels between the surface and 64.56 km (near 0.1 hPa), and the 64.56 km values are then replicated onto the four subsequent levels up to 85 km. FOAM data are on the same grid as the ocean model. Beyond initialisation the model takes no further observational data, and contains no flux corrections or relaxations to climatology. The model lacks interactive chemistry and ozone concentrations are fixed to observed climatological values averaged over 1994–2005, including a seasonal cycle from the Stratosphere-troposphere Processes and their Role in Climate (SPARC) climatology [Cionni *et al.*, 2011]. Climate forcings such as CO₂ and CH₄ concentrations are set to observed values up to 2005 and then follow the IPCC RCP4.5 scenario.

Scaife *et al.* [2014] have shown that this seasonal forecast system produces highly skillful forecasts of the North Atlantic Oscillation (NAO) during the Northern Hemisphere winter. They found the correlation of the ensemble mean DJF average NAO with observed values to be $r = 0.62$, which is statistically significant from zero at the 99% level. They argue that the combined effects of ENSO, QBO and sea-ice teleconnections, as well as the increased ocean resolution which has improved the representation of Northern Hemisphere blocking events [Scaife *et al.*, 2011b], contribute to this skill.

Hindcast accuracy is verified by comparison to the ERA-Interim reanalysis [Dee *et al.*, 2011]. As discussed in Chapter 3, the ERA-Interim data set has been demonstrated to have realistic representation of the stratospheric meridional circulation [Seviour *et al.*, 2012; Monge-Sanz *et al.*, 2013]. It also assimilates observations of ozone concentrations, and this assimilation has been demonstrated to be in close agreement with independent satellite data [Dragani, 2011]

In this chapter, hindcasts are analysed for two seasons; December–February (DJF) for prediction of the Northern Hemisphere winter stratospheric polar vortex, and September–November (SON) for the Southern Hemisphere. The SON

season is chosen because it represents the time of maximum SH ozone depletion and stratospheric polar vortex variability. For SON a 15-member ensemble of hindcasts was run for each year in the period 1996–2009, while for the DJF analysis a longer 24-member ensemble is available for the winters 1992/1993–2011/2012. The hindcast length is approximately four months from three separate start dates spaced two weeks apart and centered on 1st August (SON) or 1st November (DJF), with an equal number of members initialised on each start date. Members initialised on the same start date differ only by stochastic parameterisation of model physics, using the Stochastic Kinetic Energy Backscatter v2 [SKEB; *Bowler et al., 2009*] scheme. Details of the hindcast runs for these two seasons are summarised in Table 5.1.

Season	Hindcast period	Initialisation dates	Ensemble size
DJF	92/93–11/12 (20 years)	25/10, 01/11, 09/11	24 (8 on each date)
SON	1996–2009 (14 years)	25/07, 01/08, 09/08	15 (5 on each date)

Table 5.1: Summary table of the two sets of hindcast simulations analysed.

It should be noted that the 20-year, 20-member ensemble hindcasts of DJF were extended from a 14-year, 15-member ensemble, the same as as the SON hindcasts. These extended simulations are, however, slightly shorter than the original ensemble; ending at the beginning of March rather than the beginning of April. This therefore limits our analysis of the full ensemble so as not to include March. Furthermore, some variables were not produced by the extended DJF ensemble and so the original sorter ensemble must be used in some cases, which is made clear in the text where necessary.

In order to illustrate these hindcast simulations, timeseries of zonal-mean zonal wind (\bar{u}) at 10 hPa are shown for 60°N from November–March (Figure 5.1) and 60°S from August–December (Figure 5.2). ERA-Interim values are also shown in both cases (black lines). These are the approximate positions of the centre of the mean position of the stratospheric polar vortex in the midstratosphere, and therefore indicate the strength of the stratospheric polar vortex. In order to make the figures comparable, the shorter 14-year, 15-member ensemble is shown for the NH. It can immediately be seen that there is a much greater ensemble spread in

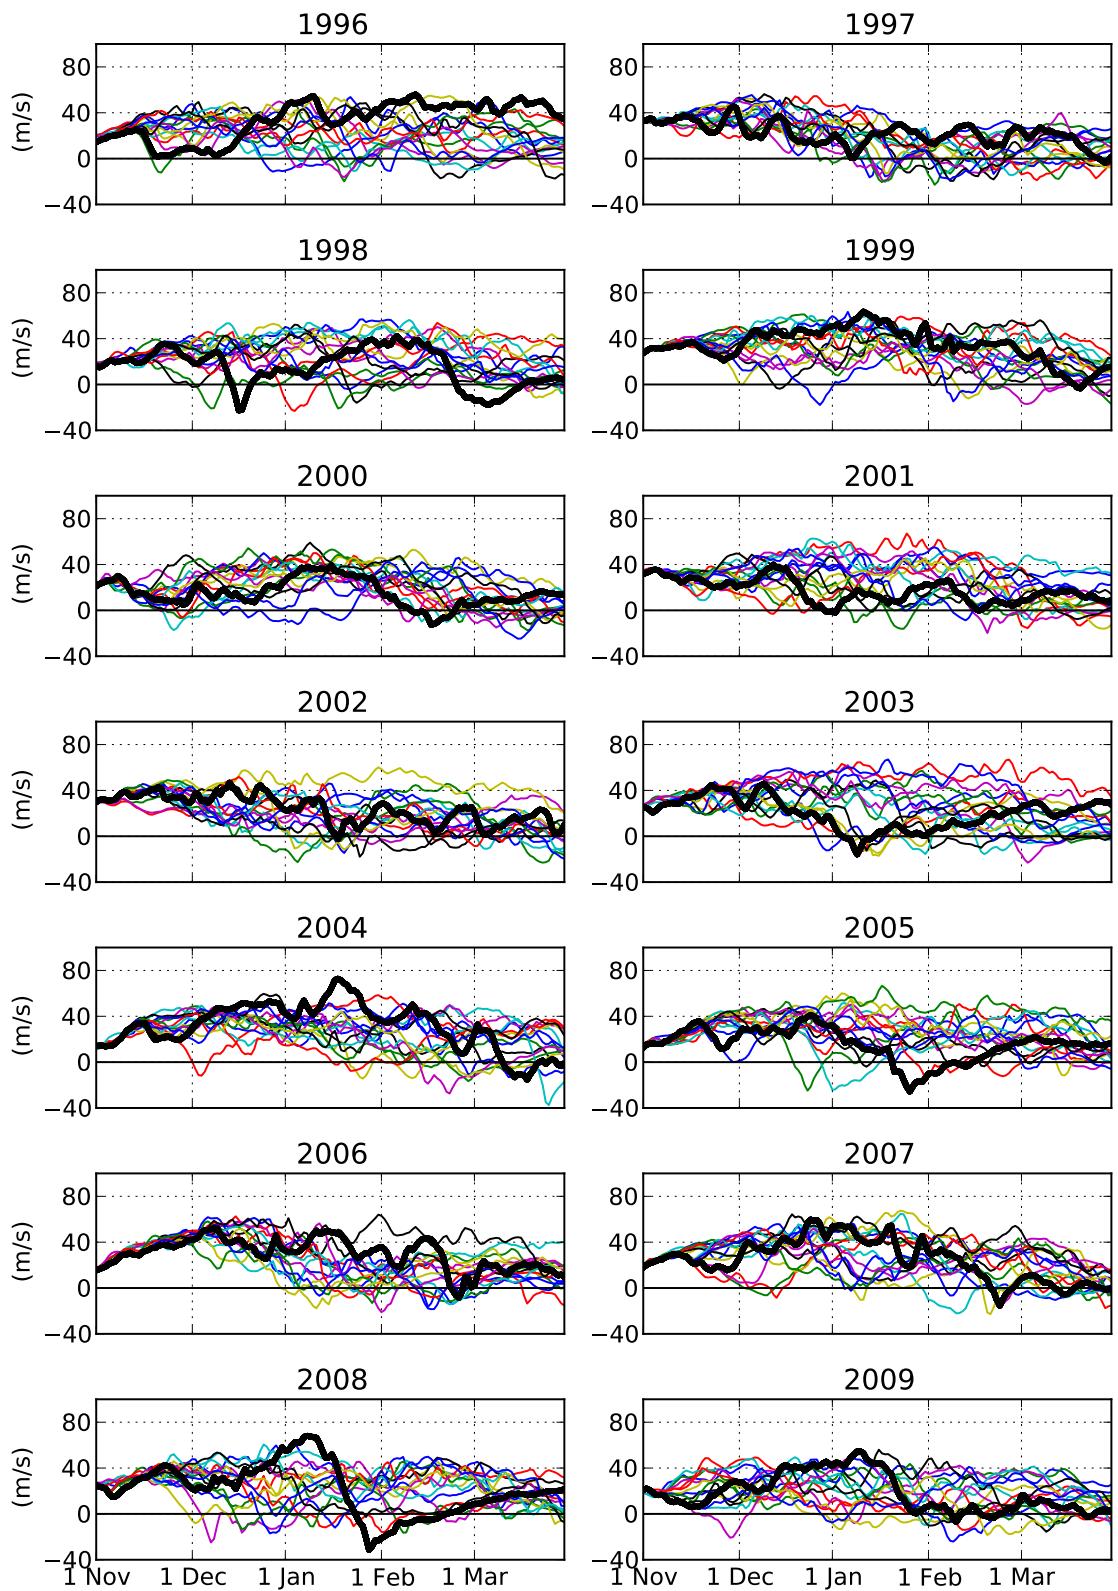

Figure 5.1: Timeseries of zonal-mean zonal wind in the Arctic polar vortex (60°N , 10 hPa) in the ERA-Interim reanalysis (thick black lines) and the GloSea5 ensemble hindcasts (thin coloured lines). Individual ensemble members are initialised from dates centred on November 1st. Years refer to the year of the initialisation date.

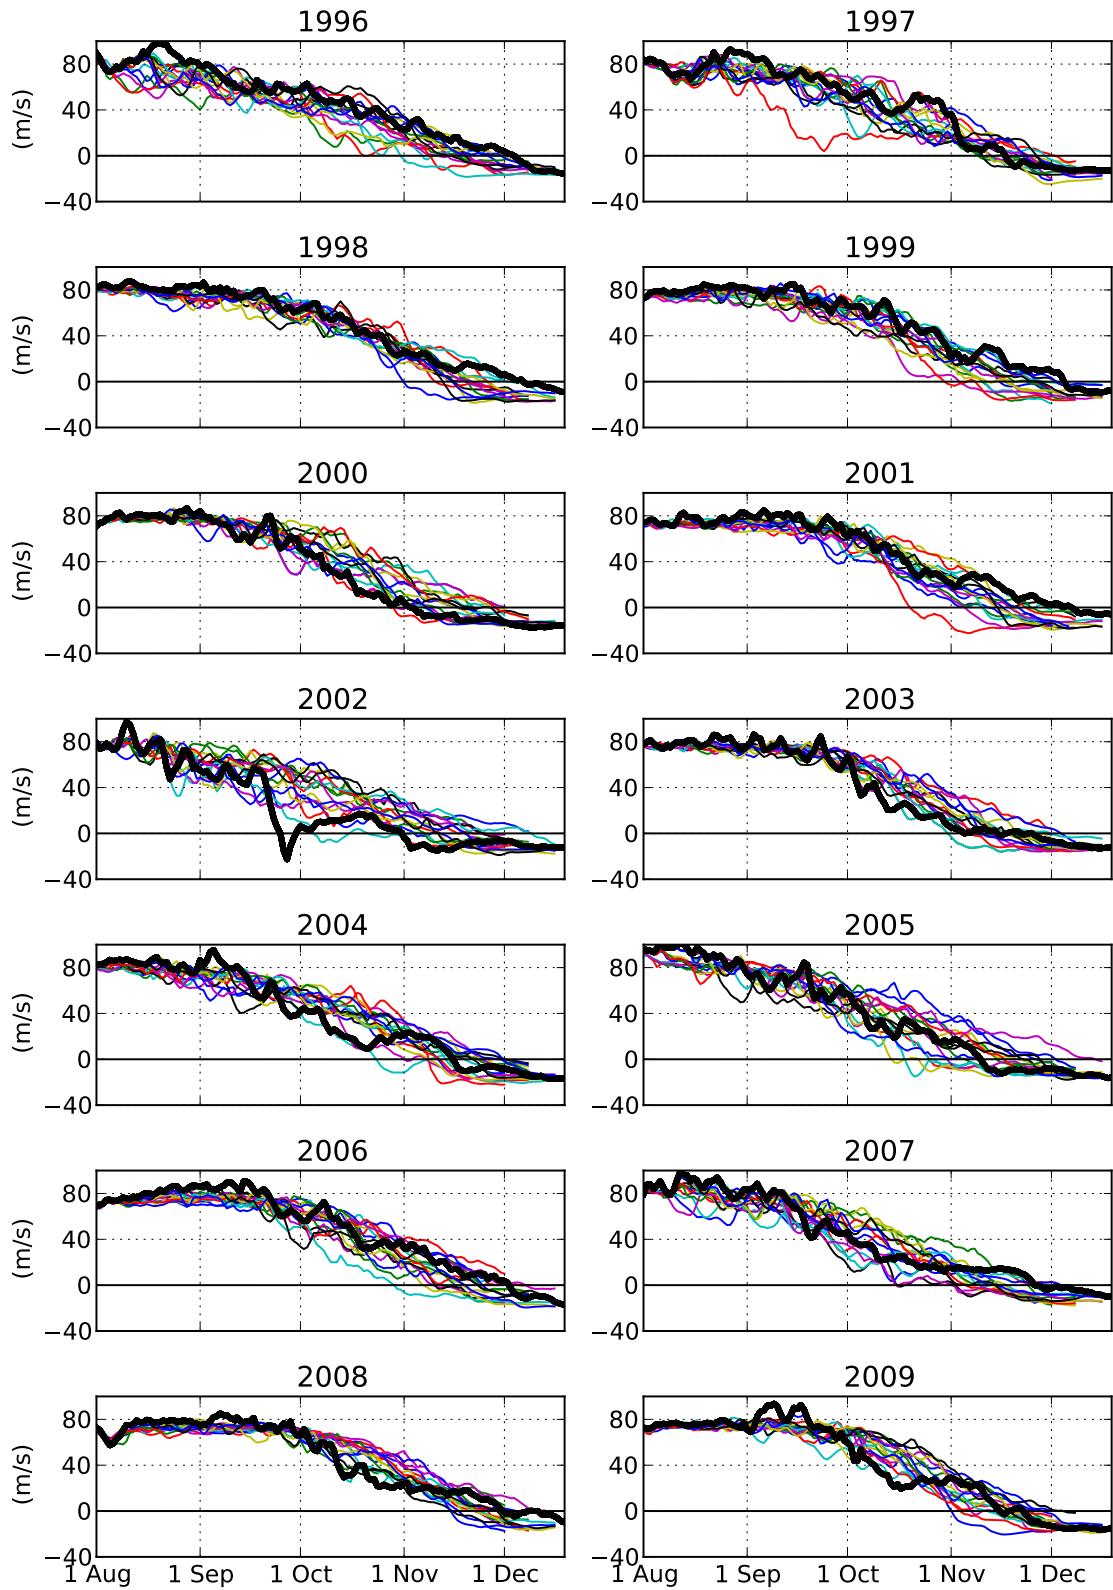

Figure 5.2: As figure 5.1 but for the zonal-mean zonal wind in the Antarctic polar vortex (60°S , 10 hPa), and ensemble members initialised from dates centred on August 1st.

5.3. NORTHERN HEMISPHERE RESULTS

the NH, owing to the much greater dynamical variability of the NH stratospheric polar vortex. In both cases it can also be seen that the ensemble spread is initially small and increases rapidly after approximately 15–30 days. This demonstrates the initial constraint to ERA-Interim and the rapid growth of small differences in initial conditions, because of the chaotic nature of the atmosphere. The predictive skill of for the Northern Hemisphere (DJF) is analysed in the next section, and the Southern Hemisphere (SON) in Section 5.4.

5.3 Northern Hemisphere results

The climatology of Arctic stratospheric polar vortex winds in the GloSea5 hindcasts is compared to the ERA-Interim reanalysis climatology in Figure 5.9. As in Figure 5.1, the strength of the stratospheric polar vortex is measured by the zonal-mean zonal wind (\bar{u}) at 60°N and 10 hPa. The composite for the GloSea5 hindcasts is formed from all the individual ensemble members over the winters 1992/1993–2011/2012 (a total of 480), while that from ERA-Interim is a composite of the same 20 winters. It can be seen that the mean, interquartile range and 95th percentile range of the GloSea5 values agree well with the ERA-Interim values, although the ERA-Interim values are noisier as would be expected from a sample size consisting of fewer years.

Figure 5.4 shows the joint distribution of the aspect ratio and centroid latitude moment diagnostics calculated over DJF from the GloSea5 hindcasts, along with the equivalent values from ERA-Interim. These diagnostics have been calculated from geopotential height following the method described in Chapter 3. Both aspect ratio and centroid latitude distributions closely match those of ERA-Interim, and the joint distribution shows the characteristic triangular shape which related to the occurrence of split and displaced vortex events. Together, Figures 5.3 and 5.4 demonstrate that GloSea5 accurately simulates the mean state and variability of the stratospheric polar vortex in the midstratosphere.

The GloSea5 hindcast predictions of interannual variability of the NH stratospheric polar vortex winds are shown in Figure 5.5. Anomalies are defined from

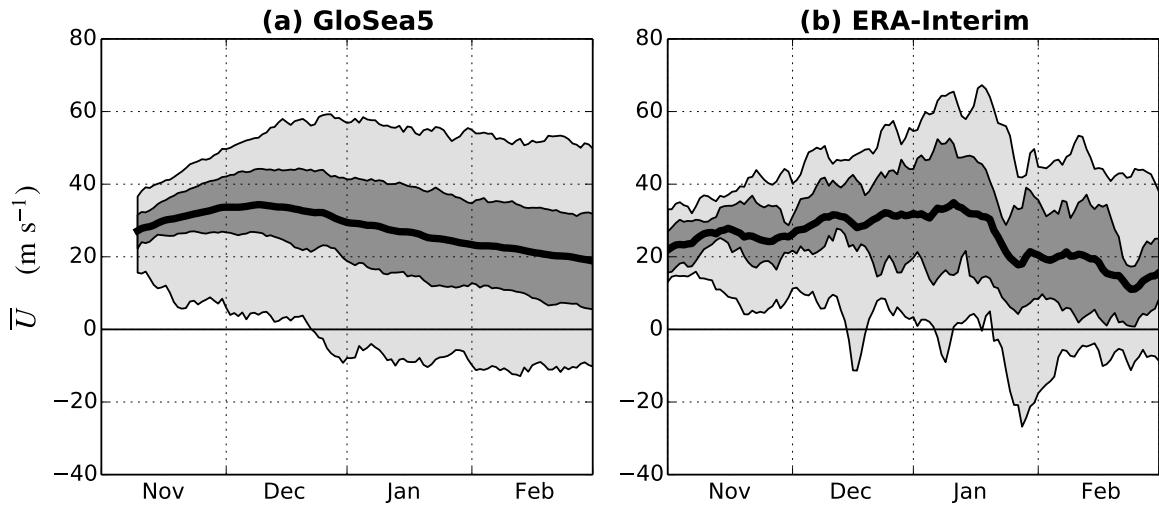

Figure 5.3: Time series of daily 10 hPa zonal-mean zonal wind (\bar{u}) at 60°N for all GloSea5 ensemble members (a) and ERA-Interim (b) from 1992–2011. The thick black line indicates the mean, dark grey shading the interquartile range and light grey the 95th percentile range.

the relevant climatology of either GloSea5 or ERA-Interim. For GloSea5, this climatology is calculated from the mean of each day across all ensemble members in all years, while for ERA-Interim the climatology is the mean of each day, smoothed with a 30-day running mean (in order to account for its increased noise due to the reduced sample size). Results are shown for DJF averages, corresponding to a 1 month average lead time. The correlation between the GloSea5 ensemble mean and ERA-Interim is $r = 0.24$ which is not statistically significant at the 95% level (under the null hypothesis that the two timeseries are uncorrelated). Significance is calculated using a two-tailed bootstrap test, whereby the percentile of the observed correlation is calculated from the distribution of correlations of a large number ($\sim 10\,000$) of pairs of time series formed by re-sampling with replacement from the original time series. As elsewhere in this thesis, these significance tests are used because they make fewer assumptions about the underlying structure of the data than parametric tests [Wilks, 2006].

Although no significant skill is found in the prediction of the seasonal mean strength of the stratospheric polar vortex, it is possible that skilful predictions of SSW events may be made. This is assessed using receiver operating characteristic

5.3. NORTHERN HEMISPHERE RESULTS

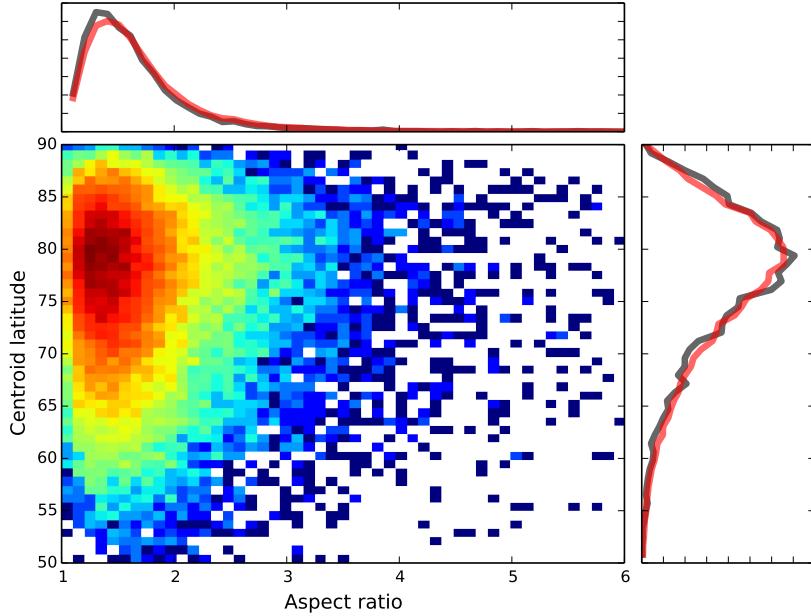

Figure 5.4: Distribution (see Figure 4.1) of the centroid latitude and aspect ratio diagnostics derived from geopotential height for all GloSea5 ensemble members (red lines) and ERA-Interim (grey lines) over 1992–2011. The joint distribution is plotted with a logarithmic colour scale such that red represents the densest regions.

(ROC) curves, a standard method in forecast evaluation [e.g., Wilks, 2006]. In order to calculate the ROC curve, the following procedure is followed:

1. For each ensemble member in each year, determine whether an SSW occurs (winters with one SSW and two SSWs are treated the same).
2. Select a threshold for the prediction of an SSW (e.g., 60% of ensemble members forecast an SSW).
3. For the given threshold determine the fraction of years for which a SSW was correctly predicted (“hit rate”) and the fraction for which a SSW was predicted but none occurred (“false alarm rate”).
4. Repeat the steps 2-3 for a range of thresholds from 0-100%.

In a skilful system the ROC curve should indicate a higher hit rate than false alarm rate, bending towards the upper left corner of the graph, while a random forecast will pass along the 1-1 line.

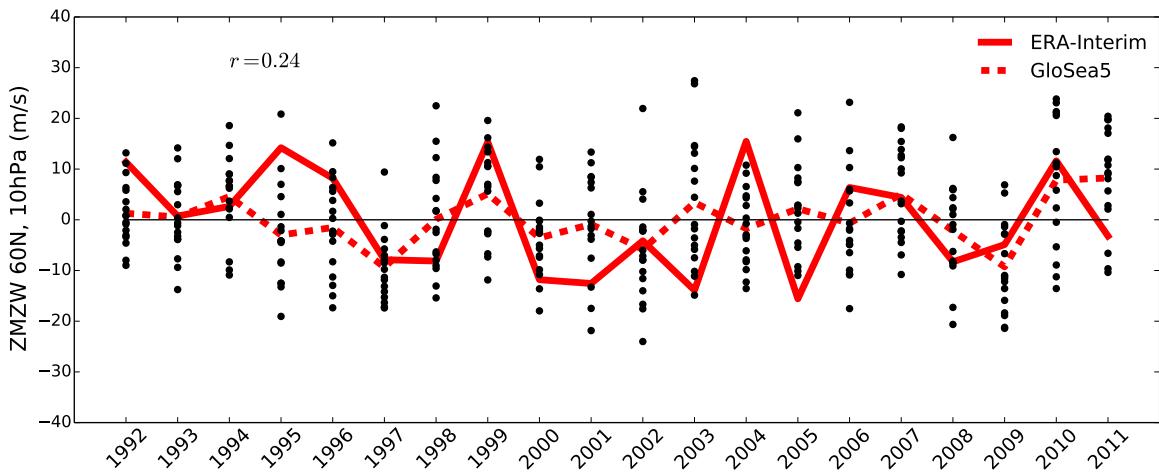

Figure 5.5: DJF mean anomalies of \bar{u} at 60°N and 10 hPa for the GloSea5 ensemble mean and ERA-Interim. Black dots represent individual ensemble members. The correlation between the GloSea5 ensemble mean and ERA-Interim is $r = 0.24$, which is not statistically significant from zero. Years refer to the year of the initialisation date.

Figure 5.6 shows the ROC curve for SSWs during DJF, determined by the traditional reversal of \bar{u} at 60°N 10 hPa, with the additional criterion that events must be separated by at least 30 days. It can be seen that the calculated ROC curve lies close to the 1-1 line indicating little skill in these predictions. This is despite quite large variations in the fraction of ensemble members predicting SSWs; from 47% (winter 2001/2002) to 100% (winter 1997/1998).

A similar analysis for the prediction of split and displaced vortex events is shown in Figure 5.7. These events have been calculated from the geopotential height-derived moment diagnostics, using the same procedure as described in Chapter 3. Again, little skill can be seen in the predictions of these events, with both ROC curves lying close to the 1-1 line. It should be noted that GloSea5 predicts a high frequency of split and displaced vortex events (8.5 events/decade; 3.5 split, 5.0 displaced), compared to the observed value of 7 events/decade. This is perhaps not surprising given the HadGEM3 model used in GloSea5 is of the same family as HadGEM2-CC, which was found to have the highest frequency of events in Chapter 4.

The evolution of NH hindcast skill as a function of lag and height is evaluated in Figure 5.8. This shows the correlation of ERA-Interim and GloSea5 ensemble

5.3. NORTHERN HEMISPHERE RESULTS

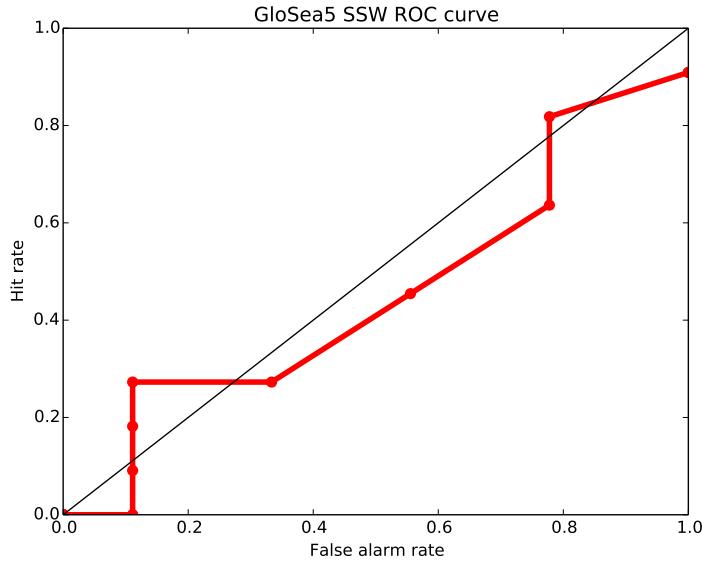

Figure 5.6: Receiver operating characteristic (ROC) curve for the prediction of SSW events during DJF for 1992–2011. SSWs are defined as a reversal to easterly \bar{u} at 60°N 10 hPa, and must be separated by at least 30 days.

mean polar cap ($60\text{--}90^{\circ}\text{N}$) average geopotential height anomalies (Z' ; which is highly correlated with the NAM [?]). Values of Z' are smoothed with a 30-day running mean before correlations are calculated, and plotted such that values for the 15th December represent the correlation of the ERA-Interim and GloSea5 ensemble mean December mean values (without this smoothing, a noisier but similar pattern of correlations is seen). Geopotential height data on several levels in the stratosphere is only available in the shorter 14-year, 15-member ensemble, and so the analysis in this figure is limited to these data. Between 1st–9th November the ensemble mean is taken as the average of the 10 initialised ensemble members, and the average of all 15 ensemble members is used after this date.

In mid-November, significant correlations are seen in Figure 5.8 in both the stratosphere and troposphere, as would be expected from the initialisation of the hindcasts from ERA-Interim data (skill is seen to rapidly decay in the tropopause region, however). This skill persists for longer in the stratosphere than the troposphere, owing to the longer timescales of stratospheric variability [e.g., *Simpson et al., 2011*], however, by mid-December no significant correlations are seen in the stratosphere or troposphere.

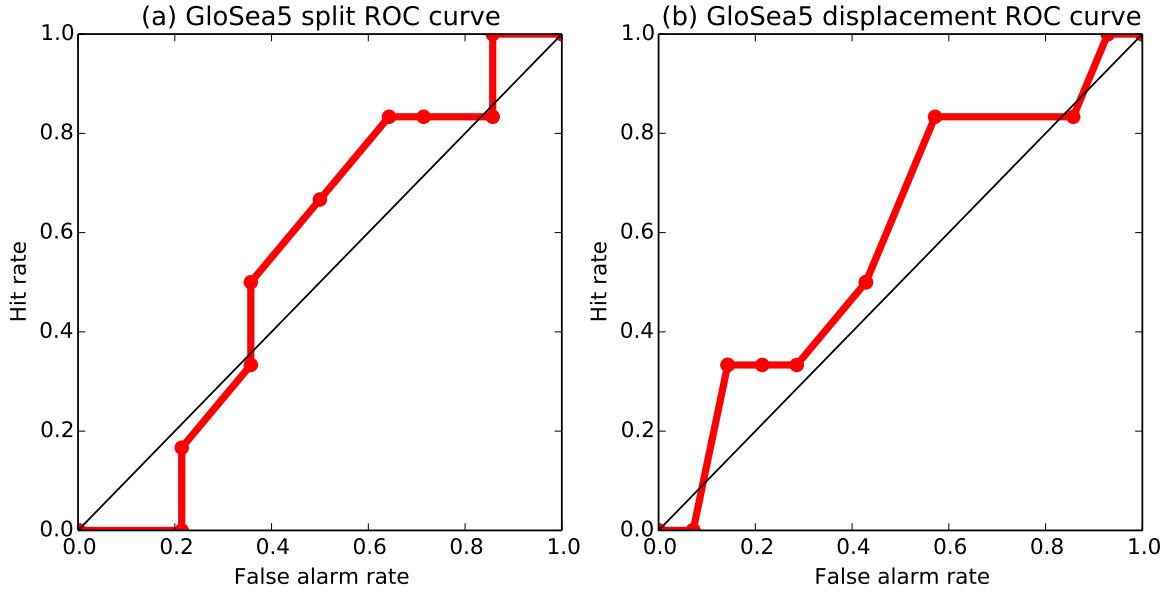

Figure 5.7: Receiver operating characteristic (ROC) curves for the prediction of split (a) and displaced (b) vortex events in all GloSea5 ensemble members over 1992–2011. Split and displaced vortex events are identified from geopotential height-derived moment diagnostics using the method described in Chapter 3.

Significant correlations return in the troposphere in late January/February, and to a lesser extent in the stratosphere. This result is similar to that for the NAO prediction in the same system, which has a greater skill in February than January (Adam Scaife, Met Office Hadley Centre, personal communication, 2013). A possible explanation for this behaviour is due to the influence of ENSO, which has been determined to have the greatest effect on the NH extratropics during late January and February [Bell *et al.*, 2009]. If indeed the influence of ENSO is important, it is not clear whether this arises from a tropospheric or stratospheric pathway, although the fact that tropospheric skill is greater than stratospheric may suggest the tropospheric pathway is more important.

Detailed analysis of the mechanisms behind the NH surface skill is beyond the scope of this chapter which investigates the role of the stratosphere. Because skill in the prediction of the NH stratosphere has been demonstrated to be low, attention is now turned to the SH. However, the implications of these results are discussed further in Section 5.5.

5.4. SOUTHERN HEMISPHERE RESULTS

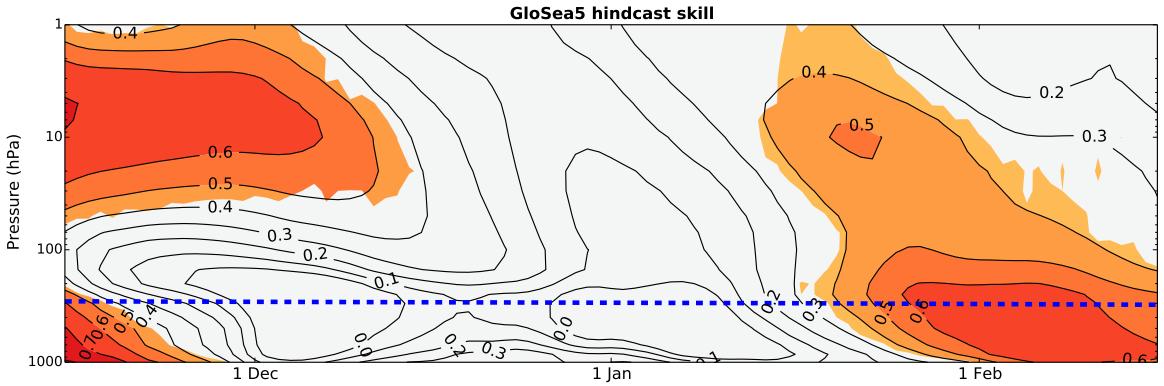

Figure 5.8: Correlation of GloSea5 ensemble mean polar cap ($60\text{--}90^{\circ}\text{N}$) geopotential height anomalies (Z') with ERA-Interim values from 1996–2009, as a function of time and height. All values are smoothed with a 30-day running mean before correlations are calculated. The contour interval is 0.1 and all colored regions are greater than zero at the 95% confidence interval, using a bootstrap test at each time at height. The blue dashed line indicates the approximate polar cap mean tropopause level [Wilcox *et al.*, 2012b].

5.4 Southern Hemisphere results

5.4.1 Stratospheric polar vortex

The climatology of Antarctic stratospheric polar vortex winds in the GloSea5 hindcasts is compared to the ERA-Interim reanalysis climatology in Figure 5.9. The strength of the stratospheric polar vortex is measured by the zonal-mean zonal wind (\bar{u}) at 60°S and 10 hPa, which is approximately the center of the mean position of the vortex in the mid-stratosphere. The composite for the GloSea5 hindcasts is formed from all the individual ensemble members over 1996–2009 (a total of 210), while that from ERA-Interim is a composite of all years from 1979–2010 (a total of 32 years). It can be seen that the mean of the GloSea5 hindcasts agrees very closely with ERA-Interim throughout the spring, with only a slight bias towards weaker winds in August and September. The interquartile and 95th percentile ranges of GloSea5 and ERA-Interim also agree well, although the ERA-Interim values are noisier as would be expected from a sample size consisting of fewer years.

The GloSea5 hindcast predictions of interannual variability of the Antarctic stratospheric polar vortex winds are shown in Figure 5.10(a). Anomalies are defined from the relevant climatology of either GloSea5 or ERA-Interim. For

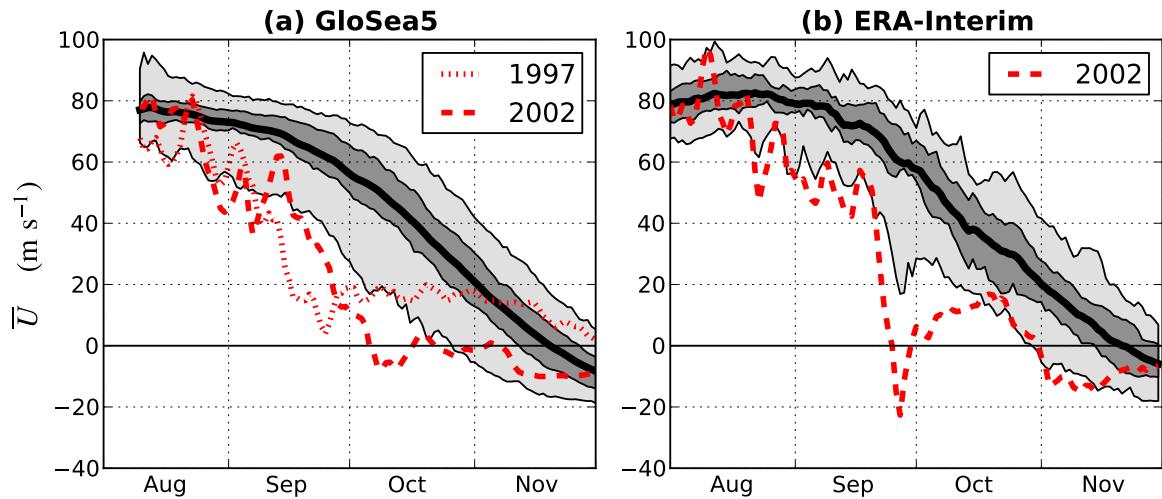

Figure 5.9: Time series of daily 10 hPa zonal-mean zonal wind (\bar{u}) at 60°S for all GloSea5 ensemble members from 1996–2009 (a) and ERA-Interim from 1979–2010 (b). The thick black line indicates the mean, dark gray shading the interquartile range and light gray the 95th percentile range. Individual time series of the ensemble member of GloSea5 for 2002 which simulated an SSW, and 1997 which simulated a near-SSW, and the year with an observed SSW (2002) are shown in red.

GloSea5, this climatology is calculated from the mean of each day across all ensemble members in all years, while for ERA-Interim the climatology is the mean of each day, smoothed with a 30-day running mean (in order to account for its increased noise due to the reduced sample size). Results are shown for September–November (SON) averages, corresponding to a 1 month average lead time. The correlation between the GloSea5 ensemble mean and ERA-Interim is 0.73, which is statistically significant from zero at the 99% confidence level, and has a 95% confidence interval of (0.37,0.90). This correlation does not depend strongly on particular years; the correlation remains significant at the 95% level ($r = 0.57$) if the year 2002 (which has the greatest anomaly) is excluded. Significance is calculated using a two-tailed bootstrap test, whereby the percentile of the observed correlation is calculated from the distribution of correlations of a large number ($\sim 10,000$) of pairs of time series formed by re-sampling with replacement from the original time series. These significance tests make fewer assumptions about the underlying structure of the data than parametric tests [Wilks, 2006], and are used throughout this study.

5.4. SOUTHERN HEMISPHERE RESULTS

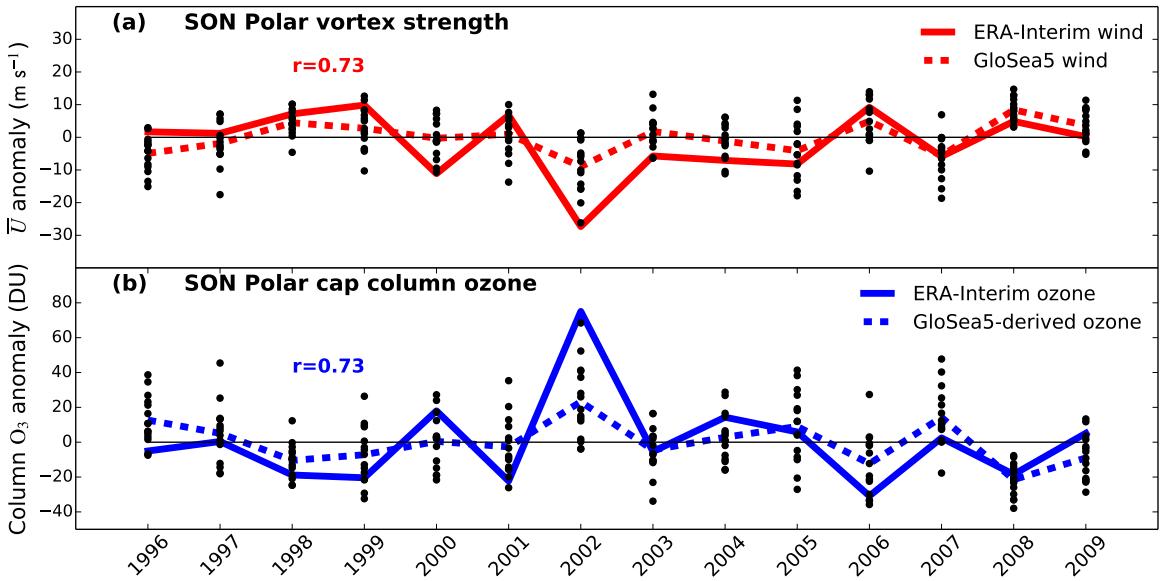

Figure 5.10: (a) SON mean anomalies at 10 hPa and 60°S in ERA-Interim and the GloSea5 hindcast ensemble mean. (b) SON mean polar cap averaged (60–90°S) total column ozone anomalies from ERA-Interim and those derived from the GloSea5 anomalies as described in the text. Individual ensemble members are shown as black dots. Hindcasts are initialized near 1st August.

The skill shown in Figure 5.10(a) cannot be accounted for by persistence of initial anomalies. In fact, there is a negative correlation between \bar{u} on 9th August, when the last ensemble member is initialised, and the SON mean ($r = -0.54$). Hence, a persistence forecast would be negatively correlated with observed values. This relationship may be consistent with ideas of a pre-conditioning of the polar vortex [e.g., *McIntyre and Palmer, 1983*]. The standard deviation of all GloSea5 ensemble members is $7.5 m s^{-1}$ and that of ERA-Interim is $9.7 m s^{-1}$ indicating that the GloSea5 ensemble spread may be too small. However, there are large uncertainties in these values due to the short hindcast period and the large 2002 anomaly.

Following *Charlton and Polvani [2007a]*, SSWs are defined as a temporary reversal of \bar{u} at 60°S and 10 hPa, occurring before the final transition to summer easterlies (final warming). Under this definition, one SSW event was simulated in the GloSea5 hindcasts, in 2002. A similar magnitude event (in terms of departure from climatology) occurred in a 1997 ensemble member, although \bar{u} did

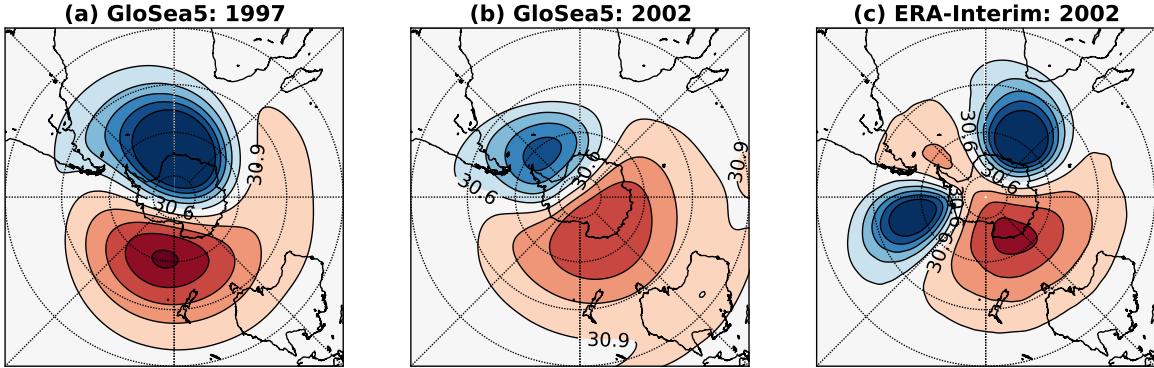

Figure 5.11: Geopotential height at 10 hPa on the date at which \bar{u} at 60°S and 10 hPa is at its minimum value, for the two GloSea5 ensemble members which simulate a SSW (a,b), and for ERA-Interim at the central date of the 2002 SSW (c). Units are km and the contour interval is 0.3 km.

not quite become easterly. Time series of stratospheric polar vortex winds for these two events are shown in Figure 5.9(a) along with the observed 2002 SSW in Figure 5.9(b). It can also be seen in Figure 5.9(a) that 2002 has the most anomalous stratospheric polar vortex in the GloSea5 hindcasts, with 14 of 15 ensemble members simulating negative anomalies, and the most negative ensemble mean. It is therefore possible that an increased likelihood the 2002 event was to some degree detectable about two months in advance, although it has not been determined whether this predictability comes from a preconditioning of the vortex, as suggested by *Scaife et al.* [2005b], or the result of external forcing.

Both the SSW events simulated by GloSea5 were vortex displacement events, in contrast to the vortex splitting event which occurred in 2002 [*Charlton et al.*, 2005]. This is demonstrated in Figure 5.11, which shows geopotential height in the mid-stratosphere at the date of minimum \bar{u} at 60°S and 10 hPa, for the two simulated events in GloSea5 and the observed event in ERA-Interim. A detailed quantitative analysis using moment diagnostics was not found necessary in this case because a qualitative inspection is possible with only two events.

The timing of the final warming of the stratospheric polar vortex also has a significant effect on stratospheric temperature and ozone concentrations [*Yamazaki*, 1987], as well as on the coupling of the stratosphere to the troposphere [*Black and McDaniel*, 2007]. The predictability of these events was investigated in GloSea5,

5.4. SOUTHERN HEMISPHERE RESULTS

but not found to be highly significant. This is probably because the mean timing of the final warming is towards the end of the four month hindcast simulation (around 20th November at 10 hPa), and the final warming does not occur before the end of the hindcast for some ensemble members, thereby introducing a bias in the mean.

5.4.2 Ozone depletion

GloSea5 does not include interactive ozone chemistry, so in order to make ozone forecasts concentrations must be inferred from other meteorological variables. Total ozone quantities over the Antarctic polar cap have been found to be highly correlated with vertical EP flux poleward of 40°S [Weber *et al.*, 2011; Salby *et al.*, 2012]. EP flux diagnostics are not routinely produced directly by operational seasonal forecast systems and requires high frequency output at high spatial resolution to calculate. However, vertical EP flux dominates variability of the stratospheric polar vortex, so it may be possible to use the strength of the vortex to infer ozone quantities.

SON mean total column ozone quantities area-weighted averaged over the polar cap (60–90°S) are shown in Figure 5.12(a) for ERA-Interim and the Total Ozone Mapping Spectrometer (TOMS) satellite instrument [Kroon *et al.*, 2008]. ERA-Interim data are highly correlated with TOMS, verifying the accuracy of ERA-Interim against direct satellite measurements (TOMS values are slightly higher than ERA-Interim; this is probably because TOMS cannot make observations during the polar night). The long-term trend in polar cap total column ozone is calculated by fitting a second-order polynomial to the data. This long-term trend is due to changes in concentrations of CFCs and other ozone-depleting substances, and largely unrelated to dynamical variability. On the other hand, shorter-term interannual changes are strongly related to dynamical variability. In Figure 5.12(b) anomalies of polar cap total column ozone from the long-term trend are plotted against anomalies of the SON mean \bar{u} at 60°S and 10 hPa. It can be seen that these two quantities are highly correlated ($r = -0.92$), meaning polar vortex variabil-

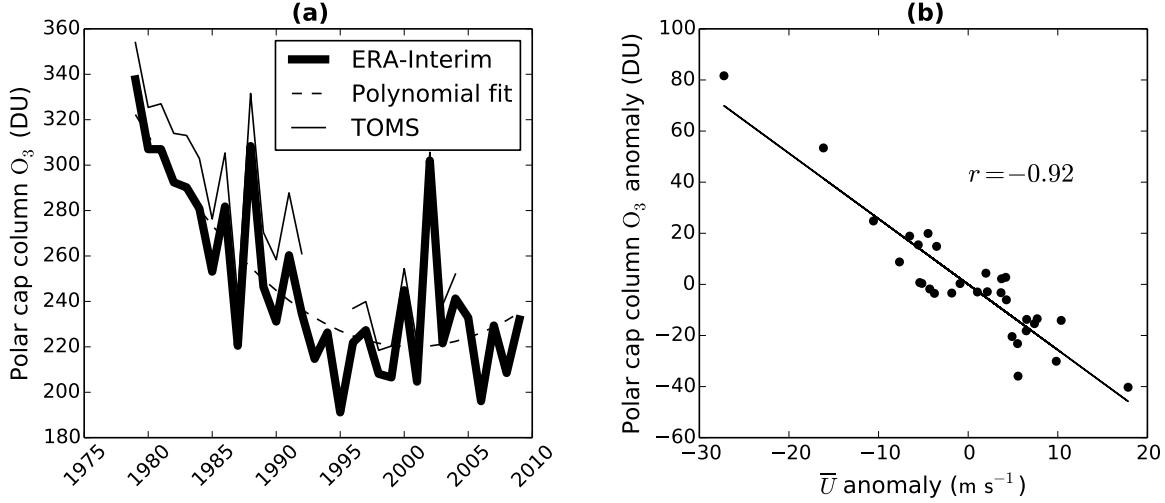

Figure 5.12: (a) Time series of SON mean polar cap averaged ($60\text{--}90^\circ\text{S}$) total column ozone in ERA-Interim and the TOMS satellite instrument. The ERA-Interim data are fitted with a 2nd-order polynomial. (b) Anomalies of ERA-Interim column ozone from the polynomial fit plotted against SON mean anomalies at 10 hPa and 60°S for each year from 1979–2009.

ity explains approximately 85% of the variance of polar cap total column ozone anomalies.

This strong correlation makes it possible to use GloSea5 forecasts of polar vortex winds to produce inferred predictions of polar cap total column ozone quantities. This is carried out by a leave-one-out cross-validation procedure [Wilks, 2006]; the linear regression of ERA-Interim ozone and \bar{u} anomalies for all years 1979–2009 except the hindcast year is used to produce the hindcast for each ensemble member. Thus no information from the hindcast year enters the hindcast itself. Figure 5.10(b) shows the GloSea5 ozone hindcasts along with the assimilated values from ERA-Interim. The correlation between the GloSea5 ensemble mean and ERA-Interim is 0.73, which is statistically significant at the 99% level, and has a 95% confidence interval of (0.38, 0.91). Errors from the regression in Figure 5.10(b) for the inferred ozone quantities for each ensemble member are small compared to the spread between ensemble members, and so are not plotted in this figure.

5.4.3 Southern Annular Mode

The SAM index in both GloSea5 and ERA-Interim is depicted as the difference between the normalized anomalies of zonally averaged mean sea-level pressure at 40°S and 65°S [Gong and Wang, 1999]. These anomalies are calculated from the respective climatologies of GloSea5 and ERA-Interim. The ERA-Interim SAM index calculated in this way is also highly correlated with other measures of the SAM, such as the station-based index of Marshall [2003]. The GloSea5 hindcast skill for the prediction of the seasonal (SON) mean SAM index is shown in Figure 5.13 . The correlation of the GloSea5 ensemble mean and ERA-Interim is 0.64, which is statistically significant at the 95% level, and has a 95% confidence interval of (0.18,0.92) confirming skillful prediction of the SAM at 1 month average lead times. This is similar to the value for the December–February (DJF) NAO correlation skill of 0.62 found by Scaife *et al.* [2014] in the same seasonal forecast system. The 1-year lag autocorrelation of the SON mean SAM is negative ($r = -0.36$), and accounting for this by sampling pairs of consecutive years in the bootstrap test leads to a narrower confidence interval than presented above. The variability of the SAM simulated by GloSea5 is broadly realistic with a standard deviation of all ensemble members of 0.98 compared to 0.90 in ERA-Interim over the same period.

The SAM is strongly related to surface temperatures over much of the SH extratropics. Figure 5.14(a) shows the correlation of the SON mean SAM from ERA-Interim over 1996–2009 with SON mean gridded station-based surface temperature data from the HadCRUT4 data set [Morice *et al.*, 2012]. The HadCRUT4 data set has been chosen to demonstrate the relationship between the SAM and surface temperature because of the scarcity of temperature observations in the Southern Hemisphere, meaning reanalysis data is poorly constrained in many regions. The same relationship between surface temperatures and the SAM is shown for the GloSea5 ensemble mean in Figure 5.14(b). Many of the observed correlations are reproduced in the hindcasts, such as the opposite signed correlations over east Antarctica and the Antarctic Peninsula/Patagonia, as well as

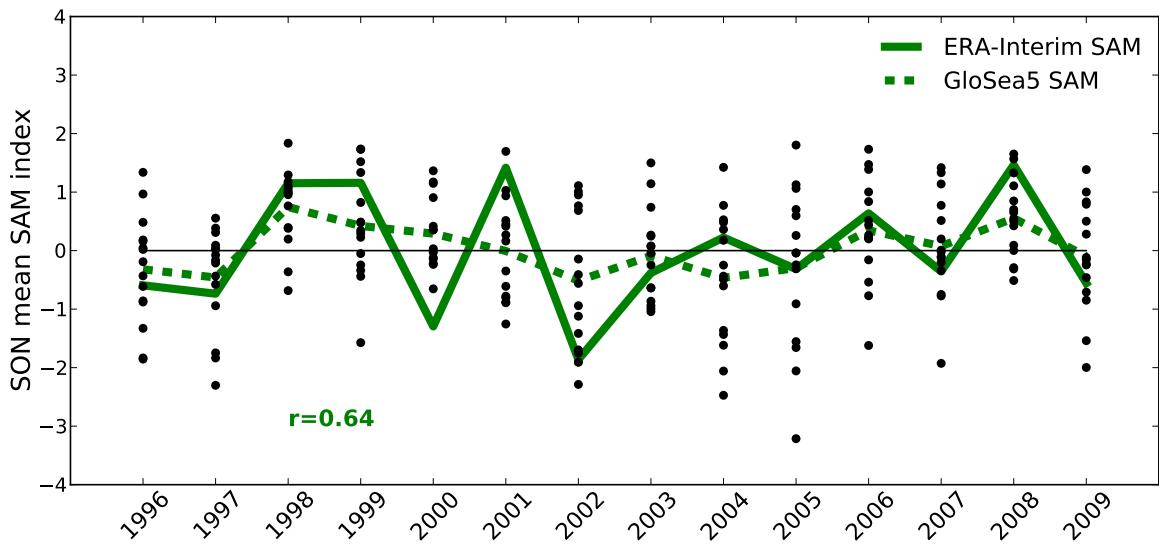

Figure 5.13: SON mean Southern Annular Mode (SAM) index in individual GloSea5 hindcast ensemble members (dots), ensemble mean (dashed green curve) and ERA-Interim (solid green curve). The SAM is calculated from mean sea-level pressure data, and hindcasts initialized near 1st August. The correlation of the ensemble mean and ERA-Interim values is 0.64, which is statistically significant at the 95% level.

between eastern Australia and New Zealand. These results are in agreement with *Gillett et al.* [2006] who analysed the temperature patterns associated with the SAM over the longer observational record of 1957–2005.

The GloSea5 ensemble mean SON surface temperature correlation with HadCRUT4 is shown in Figure 5.14(c). Also highlighted (black circles) are the points with the strongest observed correlations with the SAM ($|r| > 0.5$). Regions of significant positive correlations are found over east Antarctica, Patagonia, New Zealand, and eastern Australia. These are regions which also have a strong correlation with the SAM, indicating that the significant surface temperature skill is related to skill in prediction of the SAM. On the other hand, there are also some significant negative correlations in subtropical regions, which may indicate a model bias in the temperature pattern associated with the SAM in these regions.

5.4.4 Stratosphere-troposphere coupling

It is now investigated whether the statistically significant skill in hindcasts of the stratospheric polar vortex affects that of the surface SAM. Forecast skill as a func-

5.4. SOUTHERN HEMISPHERE RESULTS

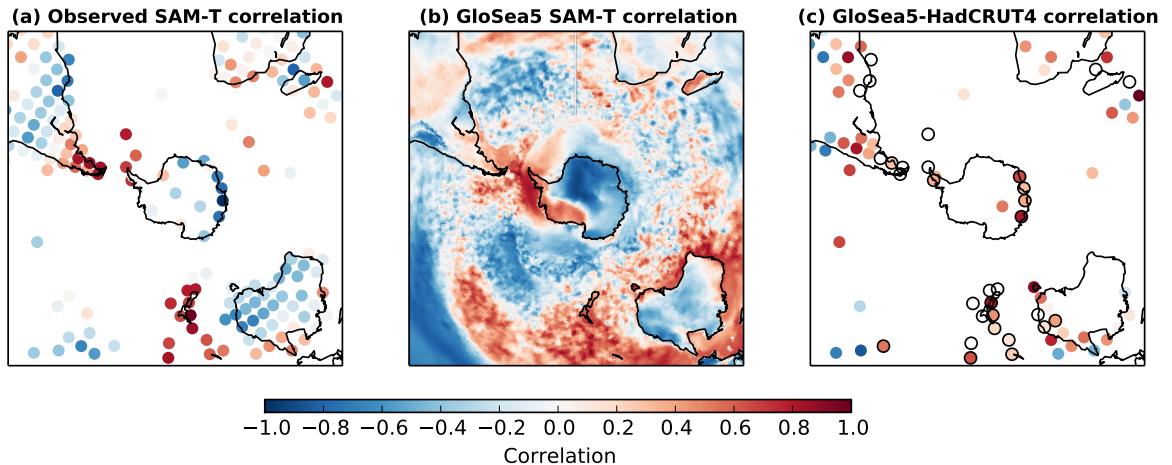

Figure 5.14: (a) Correlation of the ERA-Interim SON mean SAM with SON mean HadCRUT4 gridded station-based temperature observations over 1996–2009. (b) Correlation of the SON GloSea5 ensemble mean hindcast SAM with the SON hindcast ensemble mean near-surface temperature. (c) Correlation of observed SON mean HadCRUT4 and hindcast GloSea5 ensemble mean temperature. In (c) only correlations which are significant from zero at the 95% level according to a bootstrap test at each gridpoint are shown. Black circles represent points which have an observed correlation with the SAM with magnitude greater than 0.5.

tion of lead-time and height is studied for polar cap ($60\text{--}90^{\circ}\text{S}$) mean geopotential height anomalies (Z')¹. Figure 5.15(a) shows the correlation of Z' in ERA-Interim with the GloSea5 ensemble mean hindcast values. Values are smoothed with a 30-day running mean before correlations are calculated, and plotted such that values for 15th September represent the correlation of the ERA-Interim and GloSea5 ensemble mean September mean values (without this smoothing, there are noisier but still significant correlations in a similar pattern). Between 1st–9th August the ensemble mean is taken as the average of the 10 initialized ensemble members, and the average of all 15 ensemble members is used after this date.

As would be expected from the initialization of GloSea5 from ERA-Interim data, correlations are high in both the troposphere and the stratosphere for the August mean, due to predictability on weather timescales. However, tropospheric and lower-stratospheric skill rapidly decays and becomes statistically insignificant throughout September. In contrast, stratospheric correlations remain statistically

¹At 1000 hPa monthly mean Z' is highly correlated ($r = 0.98$) with the SAM index

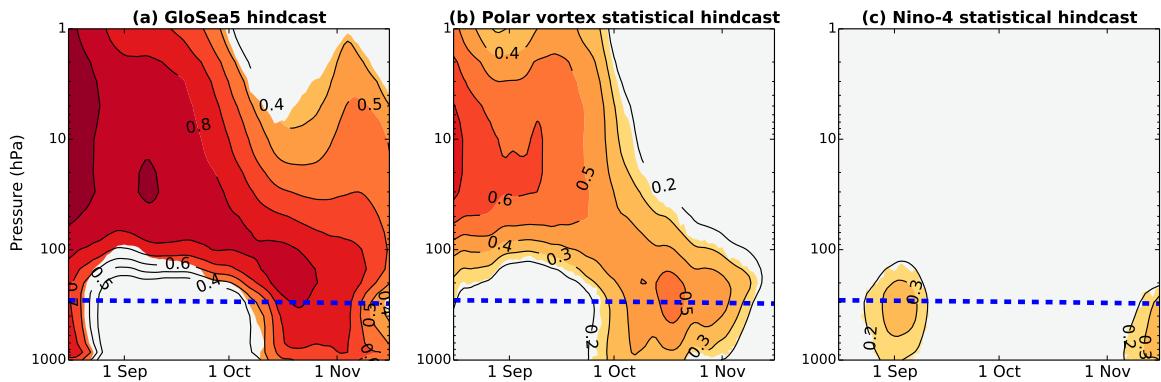

Figure 5.15: (a) Correlation of GloSea5 ensemble mean polar cap ($60\text{--}90^{\circ}\text{S}$) geopotential height anomalies (Z') with ERA-Interim values from 1996–2009, as a function of time and height. (b) Correlation of ERA-Interim from 1979–2010 values with those predicted by a linear statistical model based on Z' at 10 hPa on 1st August. (c) As (b) but based on the July-mean Niño-4 index. All values are smoothed with a 30-day running mean before correlations are calculated. The contour interval is 0.1 and all colored regions are greater than zero at the 95% confidence interval, using a bootstrap test at each time at height. The blue dashed line indicates the approximate polar cap mean tropopause level [Wilcox *et al.*, 2012b].

significant throughout the hindcast simulation, and as high as 0.8 through to mid-October (corresponding to a 2 month lead time).

Importantly, the region of high levels of stratospheric skill descends with time and is present at the tropopause at the same time as a re-emergence of significant tropospheric skill in mid-October. This re-emergence cannot be accounted for by the persistence of tropospheric anomalies, so must be the result of the effect of another predictable signal on the extratropical tropospheric circulation. An obvious candidate for such a signal is the polar stratosphere, since this remains predictable throughout the hindcast period. The re-emergence of tropospheric skill also occurs at the same time as the strongest observed coupling between the stratosphere and troposphere found in other studies [e.g., Thompson *et al.*, 2005; Simpson *et al.*, 2011].

In order to determine the stratospheric influence on tropospheric skill, a simple statistical forecast model is formed, which has as its only input the initial conditions of the Antarctic stratosphere. A leave-one-out cross validation (LOOCV) [Wilks, 2006] procedure is employed as follows:

5.4. SOUTHERN HEMISPHERE RESULTS

- i. Remove the predictand year, i , from the set of all N years, leaving $N - 1$ predictor years.
- ii. Calculate the linear regressions of Z' at 10 hPa on 1st August with Z' at all other times and heights using the $N - 1$ predictor years.
- iii. Given the value of Z' at 10 hPa on 1st August for year i (the predictand year), use the linear regressions to produce a forecast for Z' at all other times and heights for this year.
- iv. Repeat the above steps for $i = 1, 2, \dots, N$ to produce N forecasts, each with slightly different regression coefficients.

The method ensures that no information from the predictor year enters the regression, and provides an estimate of the predictability of an unknown year given the available observations. Here, ERA-Interim values are used from 1979–2009; giving $N = 32$ years.

Figure 5.15(b) shows the correlation of 30-day running means of these statistical hindcasts with ERA-Interim values. As might be expected, skill is initially high in the mid-stratosphere but not the troposphere. As with the GloSea5 hindcasts, the region of high skill descends with time, and statistically significant correlations re-emerge in the troposphere throughout October. This demonstrates that skillful forecasts of the Antarctic troposphere during October can be produced based only on knowledge of Z' in the mid-stratosphere on 1st August. It also suggests that the re-emergence of tropospheric skill in the GloSea5 hindcasts in October is likely to be caused by predictable stratospheric anomalies which descend with time.

However, it is also possible that a third factor both influences the 1st August stratosphere and the October and November troposphere. ENSO may be such a factor, since it has been shown to influence both the surface SAM [[Lim et al., 2013](#)] and the polar stratosphere [[Hurwitz et al., 2011](#)]. The influence of ENSO is therefore assessed using the same leave-one-out cross-validation procedure, and

shown in Figure 5.15(c). The input to the statistical model is the July mean Niño-4 index (sea-surface temperatures averaged over 5°S–5°N, 160°–150°W) from the HadISST1 data set [Rayner *et al.*, 2003]. Similar results are obtained using the July mean Niño-3.4 index or Southern Oscillation Index. The Niño-4 index-based statistical hindcasts show some significant tropospheric correlations around 1st September and in November, but not during October. Hence, ENSO cannot account for the October re-emergence of tropospheric skill in the GloSea5 hindcasts, at least in this statistical model.

Importantly, the longer 32-year (1979–2010) period of the ERA-Interim reanalysis (rather than the 14-year (1996–2009) period of the GloSea5 hindcasts) is used for the statistical analysis presented in Figures 5.15(b) and (c). The correlation between both the 1st August Z' at 10 hPa and the July mean Niño-4 index with the SON SAM is not statistically significantly different during 1996–2009 compared with 1979–2010. This was tested using a bootstrap test, which correlates subsets of 14 years from the (detrended) 32 years. Hence correlations found for the shorter period are deemed to be a marginal distribution of those over the longer period, so a more robust measure of sources of predictability can be obtained by studying the longer observational record. A more detailed justification for this choice of analysis period in the statistical hindcasts is given in Appendix 5.A.

Similar features are seen if the statistical hindcasts are repeated using the shorter period, although tropospheric skill from the polar vortex emerges later (in November), and that from Niño-4 earlier (in October). These statistical hindcasts also show lower skill than the GloSea5 hindcasts at almost all times in both the troposphere and stratosphere, which may indicate the importance of non-linearities or the influence of other external factors which can be captured by the full dynamical model.

5.5 Discussion

5.5.1 Northern Hemisphere

The fact that hindcasts of the NH stratospheric polar vortex have been shown to be less skilful than those of the SH is not unexpected because of the much greater dynamical variability and chaotic nature of the NH. Indeed, previous studies have not found SSWs to be predictable (in a deterministic sense) beyond about two weeks [*Marshall and Scaife, 2010; Taguchi, 2014*]. However, given the fact that the GloSea5 hindcasts have been shown to produce skilful predictions of the DJF NAO [*Scaife et al., 2014*], it is perhaps surprising that somewhat greater skill was not found in Section 5.3. Even if the vortex was to respond passively to NAO variability, a greater degree of skill might be expected.

A possible explanation for this may be that GloSea5 does not produce skilful forecasts of the North Pacific, so that the North Pacific and North Atlantic ‘destructively interfere’ in their influence on the stratosphere. However, *MacLachlan et al. [2014]* found GloSea forecasts of DJF surface temperatures to have similar skill in the North Atlantic and North Pacific, as well as the surface NAM to have similar skill as the NAO. Therefore, the reason for the relative lack of skill in hindcasts of the NH stratospheric polar vortex remains unknown. This does, however, suggest that the source of skilful DJF NAO hindcasts in GloSea5 is unlikely to be of tropospheric origin, and other model improvements such as the increased ocean resolution may be more important.

5.5.2 Southern Hemisphere

5.5.2.1 Model limitations

We have demonstrated that Antarctic total column ozone amounts are predictable up to four months in advance during the austral spring, even with a model which lacks interactive chemistry. While using such a model has the advantage of being less computationally expensive than a chemistry-climate model, there are also some drawbacks. Primarily, the model will not be able to simulate zonal asymmetries in ozone concentrations and their influence on the stratospheric circulation

or the feedback between ozone concentrations and stratospheric temperatures. Both these factors have been shown to be important in driving long-term trends in the SAM as a result of ozone depletion [Thompson and Solomon, 2002; Crook *et al.*, 2008; Waugh *et al.*, 2009].

Perhaps more relevant for seasonal forecasts is the fact that we have not been able to determine whether the observed strong correlation between the stratospheric circulation and Antarctic ozone concentrations is dominated by a chemical or dynamical mechanism. If the relationship is dominated by a chemical mechanism, whereby enhanced descent over the pole inhibits the activation of ozone-depleting substances, we would expect the correlation to weaken as concentrations of these substances return to pre-industrial levels. Accurate forecasts of ozone with models lacking interactive chemistry would then not be possible. On the other hand, if the mechanism is largely dynamical, whereby transport of ozone-rich air from the tropics is the important factor, we would not expect the relationship to change in time. Although a study to distinguish these mechanisms has been carried out for chemistry-climate models [Garny *et al.*, 2011], it has not been possible to do so in observations. In either case, we do not expect the relationship to break down soon, as concentrations of ozone-depleting substances are not projected to return to 1980 levels until the late 21st century [WMO, 2011].

5.5.2.2 Statistical significance and ensemble size

The correlation skill of 0.64 (95% confidence interval: [0.18,0.92]) for the SON mean SAM in the GloSea5 hindcasts is greater but not inconsistent with that found by Lim *et al.* [2013]. They report a correlation of 0.40 for the SON mean SAM from 1st August initialized forecasts over 1981–2010 using the Predictive Ocean and Atmosphere Model for Australia, version 2 (POAMA2). Over the comparable period of 1996–2009, they find a correlation of 0.54 (Harry Hendon, Australian Bureau of Meteorology, personal communication, 2014). Significantly, POAMA2 has only two model levels in the stratosphere, and so may be unable to simulate the stratosphere-troposphere coupling described here. Lim *et al.* [2013] attribute their results to the influence of ENSO through a tropospheric teleconnection. This

5.5. DISCUSSION

is not inconsistent with our result shown in Figure 5.15(c), since we find significant tropospheric predictability from ENSO during November, the same time that *Lim et al.* [2013] find the strongest correlation between ENSO and the SAM. The lack of discrepancy between these two systems despite their different stratospheric resolutions may be a result of the ENSO/SAM connection being too weak in GloSea5, or simply that the relatively short hindcast period used here prevents a statistically significant difference being detected.

Despite this significant correlation skill in hindcasts of the SAM, it is clear from Figure 5.13 that the standard deviation of the GloSea5 ensemble mean SAM is much less than that of observations. The signal-to-noise ratio (ratio of the standard deviation of the ensemble mean to that of all ensemble members) is just 0.4. For a ‘perfect’ forecast system (one in which observations are indistinguishable from an ensemble member), the signal-to-noise ratio, s , and correlation, r , are directly related by

$$r = \frac{s^2}{\sqrt{(s^2 + 1)(s^2 + n^{-1})}}, \quad (5.1)$$

where n is the ensemble size [*Sardeshmukh et al.*, 2000; *Kumar*, 2009]. Hence, given the value of $s = 0.4$, the expected correlation would be just 0.3, rather than the 0.64 found. This discrepancy can be explained from the fact that the average correlation between ensemble members and observations (0.27) is much greater than that between pairs of ensemble members (0.13). A similar but smaller difference is also found for the stratospheric polar vortex forecasts, and this is also observed by *Scaife et al.* [2014] for the NAO in the same system. These results mean that individual ensemble members have a smaller predictable signal than observations. This effect was recently discussed by *Eade et al.* [2014], who proposed a rescaling of the ensemble mean to have the same variance as the predictable component of the observed variance (which can be estimated by $\sigma_{obs}^2 r^2$, where σ_{obs}^2 is the observed variance). However, this procedure is most applicable to forecasts where the scaling can be determined from hindcasts, so that information from the observations does not enter the forecasts themselves. Furthermore, this rescaling does not affect correlation skill scores, and so it is not applied in the current analysis.

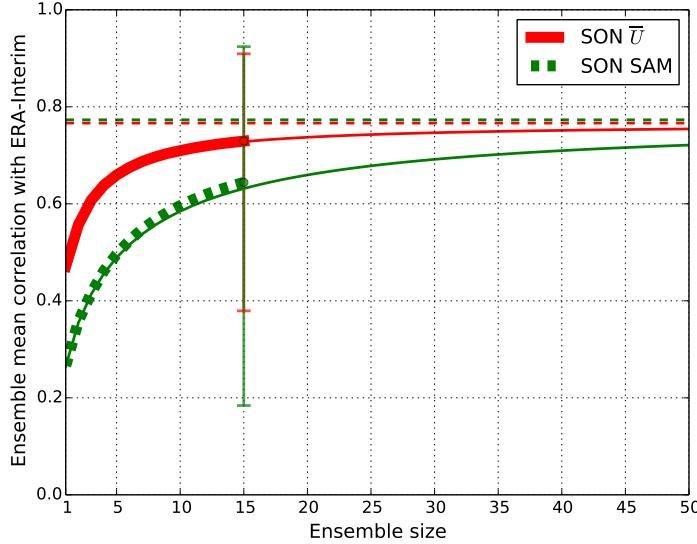

Figure 5.16: GloSea5 ensemble mean correlation with ERA-Interim as a function of ensemble size for the SON mean \bar{u} at 10 hPa and 60°S and SON mean SAM (thick lines). A theoretical estimate of the variation of correlation with ensemble size is shown in each case (thin solid lines), along with its asymptote for an infinite sized ensemble (dashed lines). Error bars represent the 95% uncertainty range for the correlation of the full 15-member ensemble, calculated using a bootstrap test.

Given the above result, it might be expected that more skilful predictions could be obtained with a larger ensemble size. To illustrate the variation of hindcast skill with ensemble size we systematically sample smaller sets of forecasts from the full 15 members for each year, following the method of *Scaife et al.* [2014]. This is repeated many times ($\sim 10\,000$) and an average value for a given sample size calculated. This variation of correlation skill with ensemble size for both the SON mean SAM and stratospheric polar vortex winds is shown in Figure 5.16. These curves closely follow the theoretical relationship of *Murphy* [1990], which relies only on the mean correlation between pairs of ensemble members, $\langle r_{mm} \rangle$, and the mean correlation between individual ensemble members and observations, $\langle r_{mo} \rangle$, given by

$$r = \frac{\langle r_{mo} \rangle \sqrt{n}}{\sqrt{1 + (n - 1)\langle r_{mm} \rangle}}. \quad (5.2)$$

These curves are shown in Figure 5.16, along with their asymptote for an infinite sized ensemble. This shows that the stratospheric forecasts cannot be greatly improved with a larger ensemble size in the current system, but greater correlation scores of the SAM could be achieved with an ensemble size near 30. Although

5.5. DISCUSSION

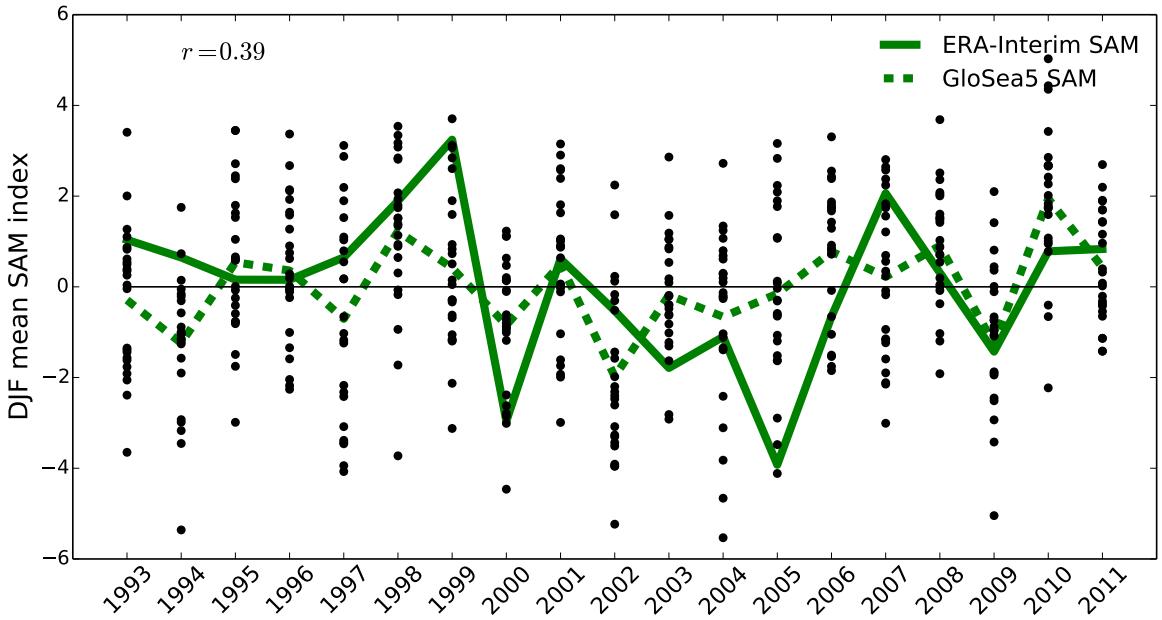

Figure 5.17: DJF mean Southern Annular Mode (SAM) index in individual GloSea5 hindcast ensemble members (dots), ensemble mean (dashed green curve) and ERA-Interim (solid green curve). The SAM is calculated from mean sea-level pressure data, and hindcasts initialised near 1st November. The correlation of the ensemble mean and ERA-Interim values is 0.39.

the large uncertainty range does not allow a strong statement about potential predictability, the asymptote near 0.8 is similar to that found by *Scaife et al. [2014]* using a longer hindcast and greater ensemble size for the DJF NAO.

5.5.2.3 Application to other seasons

The dynamics of other seasons are different to those of the austral spring, so results presented here for SON do not imply significant skill in prediction of the SAM at other times. Indeed, the 1-month lead time ensemble mean correlation of the DJF SAM with ERA-Interim is lower than that for SON at $r = 0.39$ (95% confidence interval: [0.15,0.63]), as shown in Figure 5.17. The low signal-to-noise ratio found in Figure 5.13 for SON can also be seen in Figure 5.17.

Shaw et al. [2010] found that the strongest downward wave coupling between the stratosphere and troposphere is present during September to December in the SH. They attribute this to the fact that the lower stratospheric vortex is westerly during this time, but the mid-upper stratospheric vortex is easterly (because the

final warming occurs first in the upper stratosphere) and acts as a reflecting surface for planetary waves (due to a negative refractive index; see Equation 4.4). Following the final warming in the lower stratosphere, *Shaw et al.* [2010] find wave coupling to be much weaker. *Shaw et al.* [2011] extended this analysis to also demonstrate that the dynamical influence of stratospheric ozone depletion on the troposphere through wave coupling is greatest during September–December.

On the other hand, separate studies have found that the largest tropospheric signals associated with stratospheric ozone depletion occur later, in DJF [WMO, 2011]. This may seem to contradict the findings of *Shaw et al.* [2010], but the two results can be reconciled if a different mechanism is dominant at this later time. Indeed, as well as an effect on the dynamical coupling between the stratosphere and troposphere, *Grise et al.* [2009] proposed that stratospheric ozone depletion can perturb radiative heating rates in the troposphere which can, in turn, trigger changes in tropospheric dynamics. They used a radiative model to investigate this effect and, importantly, found the largest influence on polar tropospheric temperatures to occur during DJF. A possible physical explanation for this is that it is only after the final warming, when the ozone depleted polar stratospheric air is mixed with lower latitudes, that the radiative effect on the troposphere is significant. While this was only an idealised study which lacked tropospheric dynamics, it may suggest a reconciliation with dynamical coupling being strongest from September–December and radiative from December–February.

The time dependency of SH stratosphere-troposphere coupling is further investigated in Figure 5.18. This shows lag-height correlations of polar cap Z' in the midstratosphere (10 hPa), lower-stratosphere (70 hPa) and surface (1000 hPa) at the first of each month from August–January using ERA-Interim data (1979–2010). As in Figure 5.15, values are smoothed with a 30-day running mean before correlations are calculated. Midstratosphere-leading significant correlations with the October–November troposphere are seen from 1st August (Figure 5.18(a)), as also shown in Figure 5.15. Furthermore the strongest negative lag correlations of the surface with the stratosphere occur at 1st November (Figure 5.18(l)). This

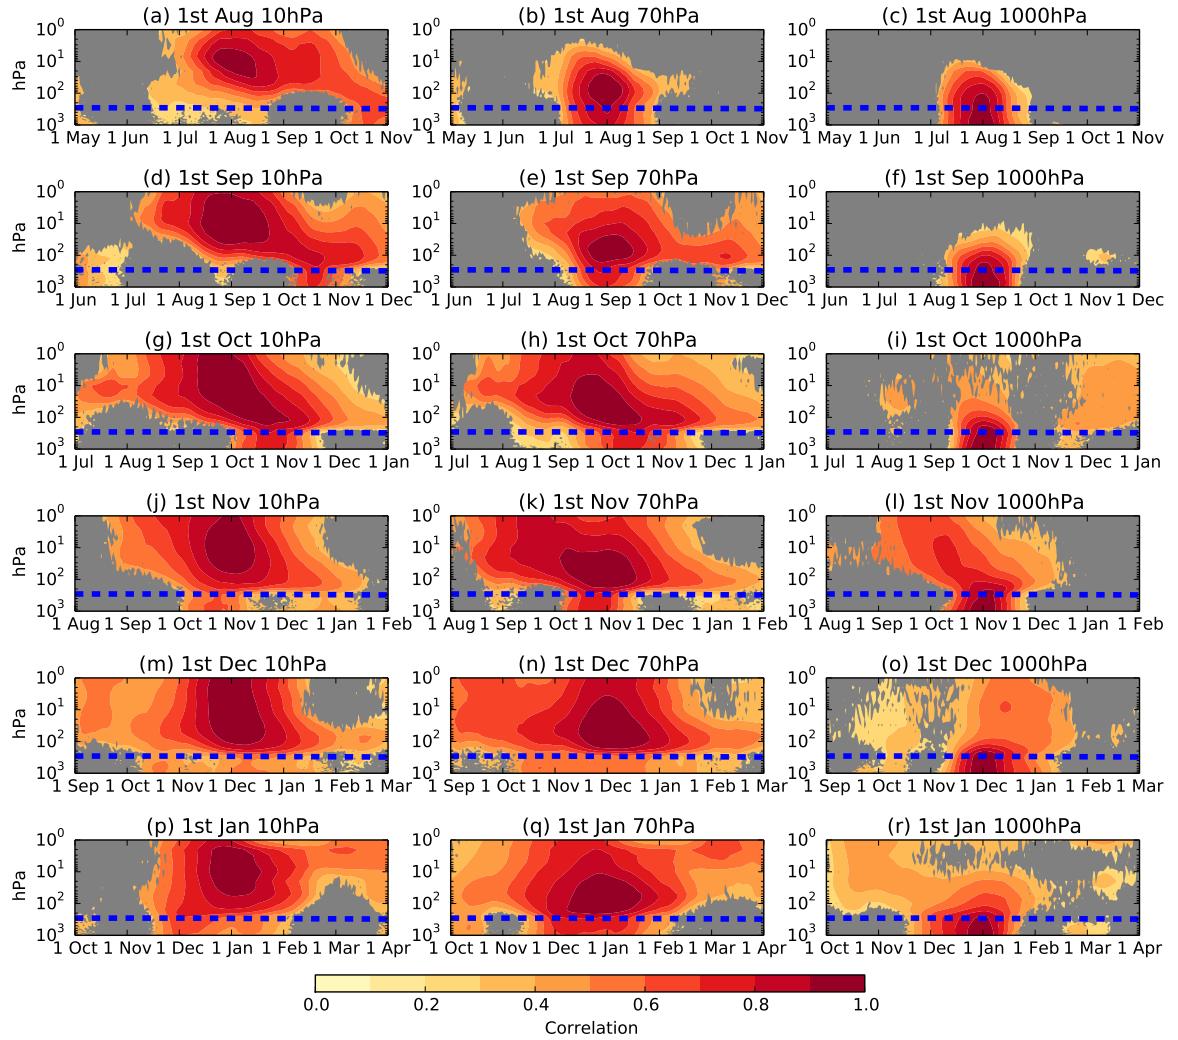

Figure 5.18: Correlation of ERA-Interim (1979–2010) Z' at 10 hPa, 70 hPa, and 1000 hPa with Z' at other times and lags. Values are smoothed with a 30-day running mean before correlations are calculated, and colours represent correlations that are 95% significant from zero according to a bootstrap test.

supports the result of *Shaw et al.* [2010] that September–December is the time of strongest stratosphere–troposphere dynamical coupling.

Similar, but weaker lag correlations are seen at 1st January (Figure 5.18(r)). This is unlikely to be due to dynamical coupling since it comes after the stratospheric final warming, and so may be a result of the radiative effect described above. It is important to note that GloSea5 does not contain interactive ozone chemistry, so the radiative effects of ozone variability will not be captured by the model. This may explain, to some extent, the reduced skill in the prediction of DJF SAM compared to the SON SAM, since the predictable effects of the stratosphere on the troposphere are not captured during DJF. Consequently, more skilful forecasts of the DJF SAM may be possible with a model including interactive ozone chemistry.

5.6 Conclusions

Motivated by the results of Chapters 3 and 4, we have analysed the predictability of the polar stratosphere and its influence on the troposphere in a set of hindcasts produced by a stratosphere-resolving seasonal prediction system. Analysis has focused on the NH for the boreal winter (DJF) and SH for the austral spring (SON), with forecasts initialised at a 1-month lead time.

No statistically significant skill was found in the prediction of the seasonal mean strength of the NH stratospheric polar vortex, or the occurrence of SSWs, split or displaced vortex events. This result may be surprising given that the same system produces skilful hindcasts of the winter NAO, which is known to influence the polar stratosphere. It does, however, suggest that this NAO skill is unlikely to be influenced by the troposphere and may be attributable to other model improvements.

On the other hand, skillful prediction of the interannual variability of the spring Antarctic stratospheric polar vortex at seasonal lead times. This includes capturing an increased likelihood of the 2002 SSW which is the most extreme year

5.6. CONCLUSIONS

in the ensemble mean and has the only ensemble member in 14 years which simulates a SSW (although another is close to simulating a SSW in 1997). Because this variability is observed to be closely correlated with Antarctic column ozone amounts, we are able to perform skillful predictions of interannual variability in Antarctic ozone depletion.

We also find significant skill in hindcasts of the spring mean SAM index. By studying the variation of this skill with time and height, we suggest that this skill is influenced by stratospheric anomalies which descend with time and are coupled with the troposphere in October and November. In fact, the influence of the stratosphere is such that skillful statistical predictions of the October SAM can be made using only information from 1st August in the mid-stratosphere.

Assuming that the 14 year period studied here is representative of future years, these results suggest that it may now be possible to make skillful seasonal forecasts of interannual variations in springtime ozone depletion and large scale weather patterns across the Southern Hemisphere.

5.A Choice of time period for statistical forecast

The aim of the LOOCV statistical analysis presented in Section 5.4.4 was to estimate the degree of predictability which arises from both the midstratosphere at the start of August and the July-mean Niño-4 index. Importantly, this analysis used the longer ERA-Interim period of 1979-2009 rather than the same 1996-2010 period over which the hindcast simulations were run. A choice of the longer period would be justifiable (and, indeed, preferable) if the relationships between these parameters and the forecast parameter (Z') are not physically different over the shorter period. That is, if the shorter period is a marginal distribution of the longer period. This is shown to be the case below.

We use the monthly Southern Oscillation Index (MSLP difference between Darwin and Tahiti, which is highly correlated with the Niño-4 index) data obtained from the Australian Bureau of Meteorology <http://www.bom.gov.au/climate/current/soihtm1.shtml>, and a station-based SAM index from the British Antarctic Survey [Marshall, 2003]. For the 1996-2009 hindcast period we find the correlation of June-July SOI with Oct-Nov SAM to be $r = 0.63$. For 1979-2010 (the ERA-Interim period) $r = 0.32$. In order to justify using the shorter hindcast period (with higher correlation), it would need to be the case that the SAM/SOI correlation is statistically significantly stronger during the hindcast period than the ERA-Interim period, so that these different correlations are not a result of random variability.

To test whether this is the case, we use a bootstrap test which randomly samples (with replacement) 14 years of detrended SAM and SOI from 1979-2013, and calculates the correlation. Figure 5.19 shows a histogram of these correlations along with the 1996-2009 correlation. The 1996-2009 value is not inconsistent with random variability at the 95% level for either a one- or two-tailed test. Therefore we conclude that the SAM/SOI correlation is not statistically significantly greater for 1996-2009. As such the 1996-2009 correlation is a marginal distribution of 1979-2013 so we include the longer ERA-Interim period in our analysis to provide a more robust measure of sources of predictability.

5.A. CHOICE OF TIME PERIOD FOR STATISTICAL FORECAST

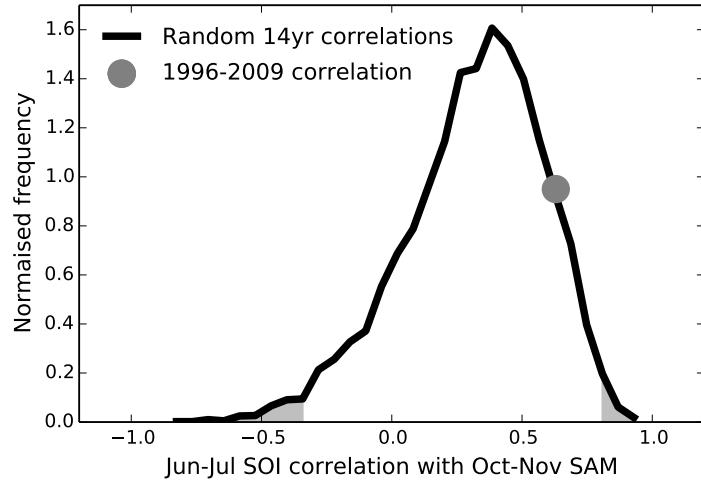

Figure 5.19: Histogram of correlations of random 14-year samples of detrended June-July SOI with October-November SAM. Also shown is the correlation over the 1996–2009 hindcast period. Grey shading indicates the < 2.5% and > 97.5% ranges.

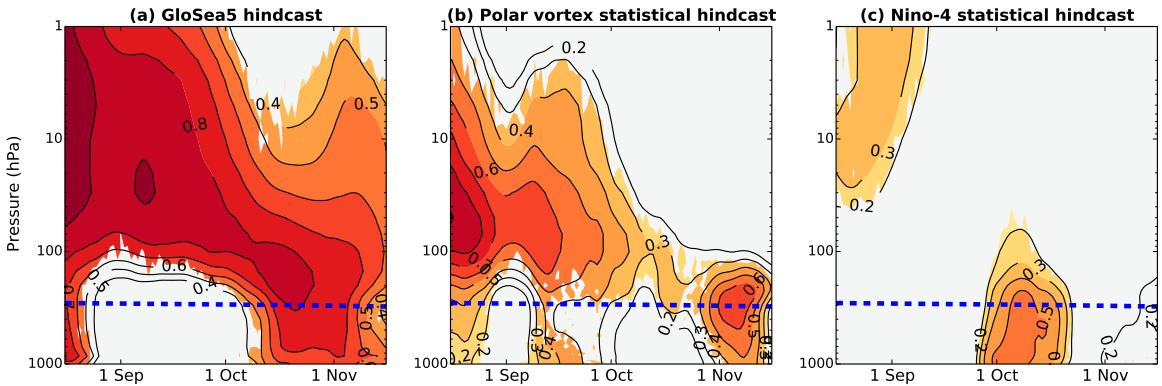

Figure 5.20: As Figure 5.15 but all analysis restricted to the 1996–2009 period.

For completeness we include a figure with the same analysis limited to 1996–2009 in this appendix (Figure 5.20). Similar features as Figure 5.15 can be seen although tropospheric skill emerges later in Figure 5.20(b) and earlier in Figure 5.20(c).
