CHAPTER 1

A geometrical description of vortex variability

1.1 Introduction

Stratospheric sudden warmings (SSWs) are extreme events in which the strong westerly winds that usually dominate the winter polar stratosphere become highly disturbed (here, for reasons outlined below, we use the term SSW to encompass a wider range of variability than its traditional definition). These events lead to the mixing of mid-latitude air into the polar vortex region, causing an increase in temperatures by several tens of kelvin over the course of a few days. Traditional methods to identify stratospheric sudden warmings (SSWs) have relied on either zonal-mean [*Andrews et al., 1987*] or annular mode [*Baldwin and Dunkerton, 2001*] diagnostics. Neither method explicitly deals with the inherent zonal asymmetry in vortex variability. In particular, SSWs are observed to occur in one of two manners: displaced vortex events, where the vortex moves far from the pole, and split vortex events, where the vortex separates into two ‘child’ vortices. These two types have a very different spatial structure and evolution timescale [*Matthewman et al., 2009*]. Displaced and split vortex events are predominantly associated with vertically propagating Rossby waves of wavenumber 1 and 2 respectively, and many previous studies have classified SSWs based on wavenumber [e.g. *Nakagawa and Yamazaki, 2006*]. However, this method does not provide a description of the location of the polar vortex itself, which theoretical arguments suggest may be important for understanding stratosphere-troposphere coupling [*Amбаум and Hoskins, 2002*]. In an improvement to these traditional SSW definitions, *Charl-*

ton and Polvani [2007] (hereafter CP07) introduced a classification in which a split vortex event is identified when two vortices with a circulation ratio of 2:1 or higher are present, and all other SSWs are automatically classed as displaced vortex events. However, they maintained the traditional SSW identification which requires there to be a reversal of the zonal-mean zonal wind at 10 hPa and 60°N.

An increased understanding of stratospheric variability can be gained by using vortex-centric diagnostics, such as two-dimensional (2D) vortex moments [*Waugh, 1997; Waugh and Randel, 1999; Mitchell et al., 2011a,b*], which provide a geometrical description of the vortex and have no reliance on zonal-mean properties. Using a classification based on these diagnostics, *Mitchell et al. [2013]* (hereafter M13) identified a greater number of SSWs than CP07. This is primarily because they did not use a zonal mean threshold criterion. Importantly, M13 also demonstrated that split vortex events penetrated deep into the troposphere and resulted in significant surface anomalies, while anomalies associated with displaced vortex events do not descend far below the tropopause. Their result supported a similar conclusion by *Nakagawa and Yamazaki [2006]*, who found that the impact of events associated with an enhanced upward flux of wavenumber-2 planetary waves was more likely to reach the surface. These results underline the need to correctly identify the precise type of SSW, in order to understand stratosphere-troposphere coupling within climate models.

Distinguishing between displaced and split vortex events using the method of M13 requires the use of potential vorticity (PV), which is not commonly output by climate models. For this reason, previous attempts to apply PV-based techniques in a multi-model study have led to the majority of models being excluded [*Mitchell et al., 2012*]. Furthermore, their method used a hierarchical clustering technique [*Hannachi et al., 2010*], which is very sensitive to the exact shape of the distribution of vortex variability, so is unsuitable for application to a range of models with different climatologies. In this chapter, we develop an improved method which; (a), is based on the geometry of the vortex, but requires only the 10 hPa geopotential height; and (b), identifies events using a simple threshold instead of a clustering technique. We apply this new method to the ERA-40 and ERA-Interim reanalysis datasets and demonstrate that the method captures a similar number of events which are in good agreement with, and at least as extreme as, those of M13.

1.2 The Z_{10} method

1.2.1 Vortex geometry calculation

Northern Hemisphere winter daily-mean data for December-March (DJFM) were employed. The European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-40 dataset [*Uppala et al., 2005*] is used from 1958-1979 and ERA-Interim [*Dee et al., 2011*] from 1979-2009. The geometry of the vortex is described in terms of the latitude of the centre of the vortex (centroid latitude) and aspect ratio (a measure of how stretched the vortex is).

The method calculates the 2D vortex moment of order $a + b$, defined in Cartesian coordinates as

$$\mu_{ab} = \iint_S [X(x, y) - \bar{X}] x^a y^b dx dy, \quad (1.1)$$

where \bar{X} is a single contour of PV or geopotential height, representing the vortex edge. The value of this contour is chosen to match that of the 10 hPa geopotential height (Z_{10}) or 850 K PV (PV_{850}) DJFM zonal-mean at 60°N (however, the results are not sensitive to the exact choice of contour between about 50°-70°N). Following the method of *Matthewman et al. [2009]* (to which readers are referred for technical details), Equation 1.1 allows for the explicit calculation of the centroid latitude and aspect ratio on a particular pressure level or isentropic surface. Other moment diagnostics can be extracted, such as vortex area and kurtosis, but these were not found necessary for identifying split and displaced vortex events, and are therefore omitted from the analysis.

Figure 1.1 compares the distribution of aspect ratio and centroid latitude, calculated using daily PV_{850} and Z_{10} . The centroid latitude distributions are almost identical, with a peak around 80°N. The aspect ratio distributions have a similar shape, with a peak at about 1.3, but the PV based diagnostic has a larger tail. This is to be expected, since the PV field contains more small-scale, filamentary structures than geopotential height. Neither distribution shows bi-modality, suggesting that the application of clustering techniques, as in *Coughlin and Gray [2009]* and *Hannachi et al. [2010]*, may be inappropriate. As well as having similar distributions, the timeseries of the PV and geopotential height derived diagnostics (not shown) are well correlated, with correlation coefficients of 0.9 for centroid latitude and 0.6 for aspect ratio.

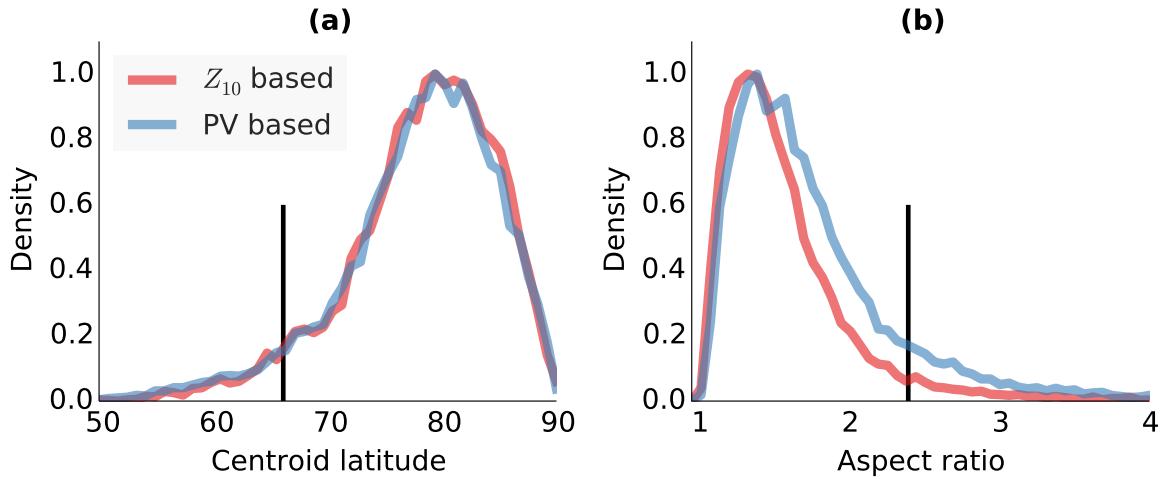

Figure 1.1: Distributions of the December-March centroid latitude (a) and aspect ratio (b), of the Northern Hemisphere stratospheric polar vortex over 1958-2009. Diagnostics are calculated from geopotential height at 10 hPa (Z_{10}) and potential vorticity at 850 K (PV). Thresholds of 66°N in centroid latitude and 2.4 in aspect ratio are used to define events, and are indicated by the black vertical lines.

1.2.2 Event definition

In order to identify displaced and split vortex events, a threshold criterion is introduced and applied to the geopotential height derived diagnostics. A displaced vortex event requires the centroid latitude to remain equatorward of 66°N for 7 days or more. A split vortex event requires the aspect ratio to remain higher than 2.4 for 7 days or more. These thresholds are indicated in Figure 1.1, and were selected to give a similar frequency of displacement and splitting events as M13. This choice is somewhat subjective, but the results presented below are not sensitive to the exact choice of threshold. There were no occasions on which both criteria were met simultaneously. The onset date is defined as the day that the appropriate threshold is first exceeded, and to ensure that no events are counted twice, the events are required to be spaced at least 30 days apart, chosen to reflect radiative timescales in the lower stratosphere [Newman and Rosenfield, 1997]. *Mitchell et al.* [2011a] found that the aspect ratio and centroid latitude follow an extreme value distribution [Coles, 2001] and we note that both thresholds chosen here lie beyond the extreme value thresholds of their respective distributions. Using this method, 17 displaced and 18 split vortex events (listed in Table 2.1) are identified over the 52 winters, an average of 7 per decade. These events are all mid-winter events – the DJFM data were used explicitly to avoid counting final warmings. This frequency lies between the values of CP07 (6/decade) and M13

1.3. ANALYSIS

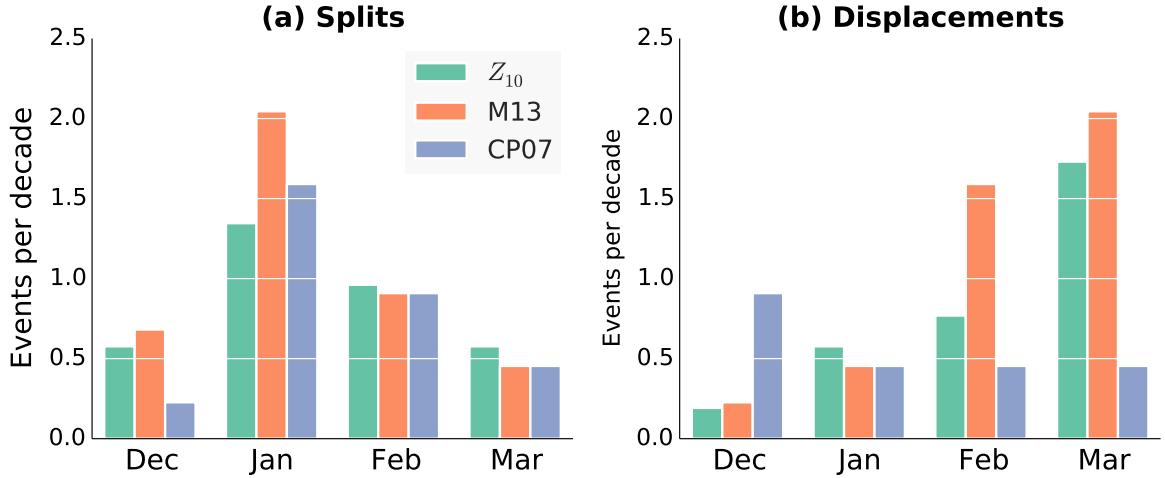

Figure 1.2: Histogram of the seasonal distribution of displaced and split vortex events, from the Z_{10} method, M13 and CP07.

(8/decade).

There are significant differences in the seasonal distribution of displaced and split vortex events, as shown in Figure 2.7. Split vortex events are more frequent in early-mid winter, with a peak in January, while displaced vortex events are skewed towards late winter. Figure 2.7 also shows the seasonal distribution of displaced and split vortex events from CP07 and M13. The shape of the distribution agrees well with the seasonal distribution found by M13 for both types of event. However, there is less similarity with the CP07 distribution of displaced vortex events (Figure 2.7b). CP07 indicates an approximately flat distribution throughout winter, and many fewer displaced vortex events overall. It should be noted that the seasonal distribution of displaced and split vortex events from the moment based methods does not arise from the underlying climatology of centroid latitude or aspect ratio, which remains approximately constant throughout winter [Mitchell *et al.*, 2011a].

1.3 Analysis

To evaluate how well the new method captures displaced and split vortex events, Figure 1.8 shows composites of PV in the mid-stratosphere (850 K) following their onset dates. These are averaged over the 5 days following the onset date for split events and 7 days for displaced events (these averaging periods reflect the different timescales of the events). The composites are compared with the corresponding composites following the events identified by M13 and CP07. For the split

| No. | Event onset | Event type | ΔT_{10} (K) |
|-----|-------------|------------|---------------------|
| 1* | 1961-3-9 | D | 10.2 |

Table 1.1: A summary table of displaced (D) and split (S) vortex events, identified using the Z10 method for data from 1958-2009. ΔT_{10} represents the mean area-weighted 50°-90°N cap temperature anomaly at 10 hPa calculated 5 days either side of the event onset date. Stars represent those numbers that do not coincide (within 10 days) with events defined by CP07.

1.3. ANALYSIS

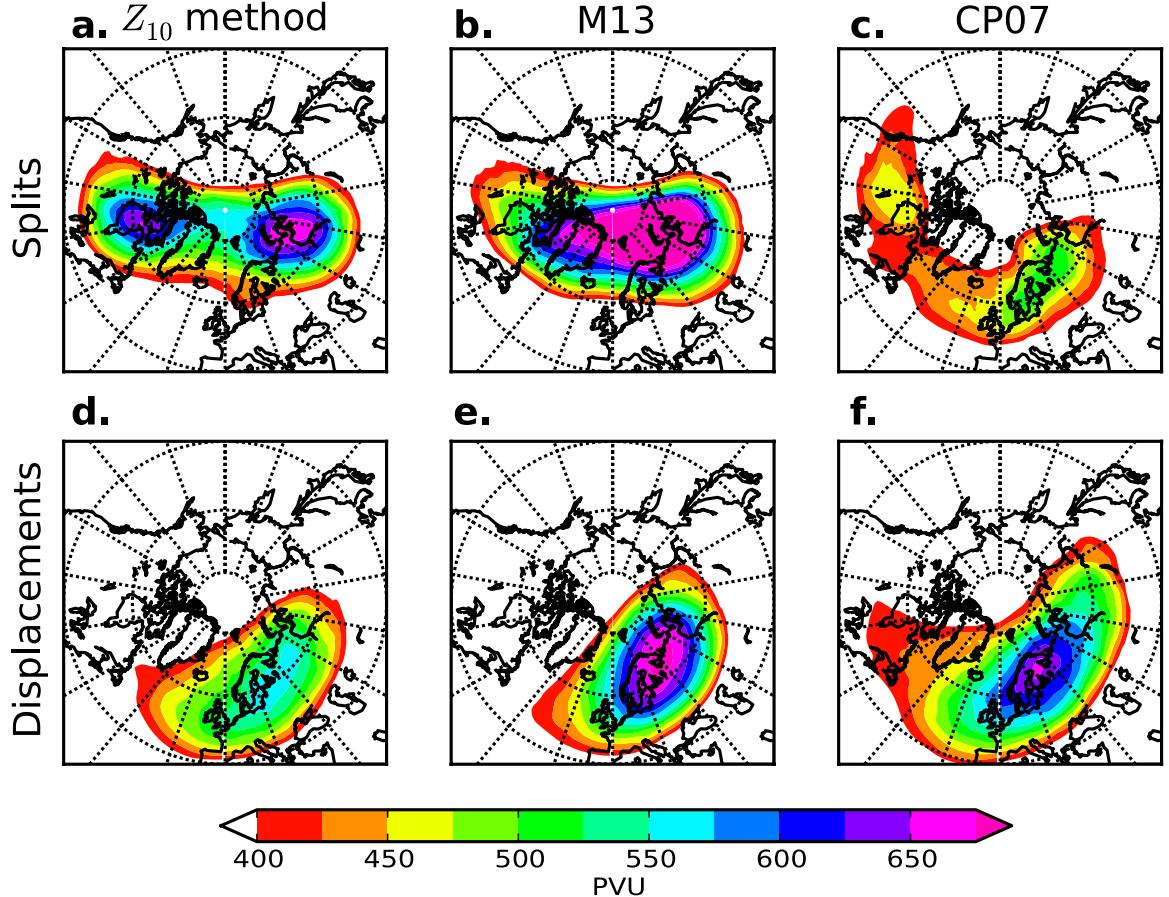

Figure 1.3: Composites of potential vorticity at the 850 K isentropic surface from the ECMWF reanalyses over 1958-2009. Composites are taken over the 5 days following the onset date of split vortex events (a,b,c) and 7 days following displaced vortex events (d,e,f) (the difference is due to the different timescales of these events). We compare the current (Z_{10}) method (a,b) with that of M13 (b,e) and CP07 (c,f).

vortex events, the Z_{10} method clearly shows two separated vortices, one centred over Canada and the other over Siberia. This characteristic direction reflects the climatological wave-2 pattern at this altitude. For the M13 events the split vortex composite shows the vortex stretched across the same 90°W - 90°E line, although not as clearly split, while the composite for the CP07 events looks very different. This has a weak vortex centred over Canada, with the other over Northern Europe, and is similar to the composite for displaced events. All three composites for displaced events show a vortex centred over Northern Europe, but this extends most westward in the CP07 composite, suggesting that there may be some contamination from misdiagnosed split vortex events.

Figure 1.8 demonstrates that the Z_{10} method succeeds in identifying displaced and split vortex events as well as, and in some cases better than, the meth-

ods of M13 or CP07. When comparing the three methods, CP07 is the clear outlier. This is most likely because the CP07 approach employs a zonal-mean threshold which cannot accurately capture the extreme events (M13).

1.4 Summary

Recent research has demonstrated the need to distinguish between displaced and split stratospheric polar vortex events, due to their different impacts on surface weather patterns. However, current methods to identify these events are complex or require non-standard variables. In this chapter, a new, robust method has been developed to identify displaced and split vortex events, which requires only geopotential height at 10 hPa. The method is briefly summarised as follows:

1. To identify the vortex region, a single contour of 10 hPa geopotential height is selected: the value of the zonal mean at 60°N.
2. Using this contour and the geopotential height field, the centroid latitude and aspect ratio are calculated, following the methodology of *Matthewman et al.* [2009].
3. Events are identified using a threshold criterion: Displaced events are identified if the centroid latitude remains equatorward 66°N for 7 days or more. Split events are identified if the aspect ratio remains above 2.4 for 7 days or more. No two events may occur within 30 days.

Results using this method demonstrate that it is able to identify split and displaced vortex events at least as effectively as previous methods.

1.4. SUMMARY

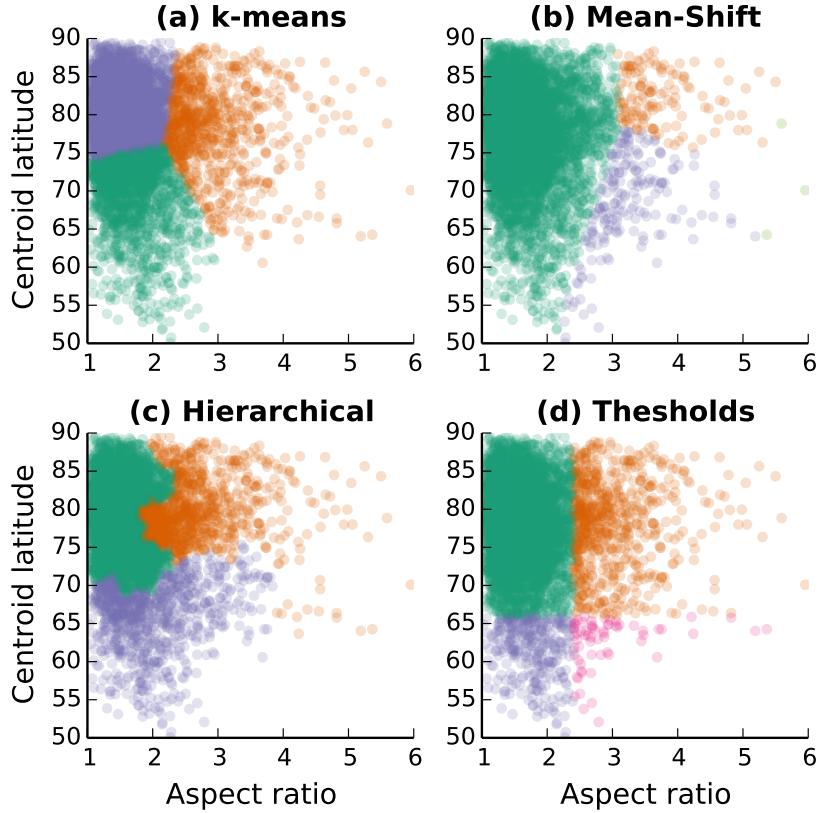

Figure 1.4: Three clustering algorithms and a threshold division applied to the moment diagnostics in centroid latitude-aspect ratio space. For the *k*-means and hierarchical algorithms three clusters were specified. The mean-shift algorithm determined the number of clusters to be 4.

M13 found that the mean sea-level pressure (MSLP) anomalies are different before and after displaced and split vortex events. In Figure ?? we present composites of MSLP 30 days before and 30 days following the onset dates of displaced and split vortex events, calculated using the Z_{10} method, from the ECMWF re-analyses. Statistical significance is estimated from a Monte-Carlo method, using 10^5 composites of equal size, formed from randomly sampled winter dates. The strongest precursor is found for displaced vortex events, with a wave-1 pattern that is similar to the stationary wave pattern [e.g. *Garfinkel and Hartmann, 2008*], suggesting increased wave-1 propagation into the stratosphere. However, the strongest anomalies following events occur after split vortex events, with a pattern resembling the negative phase of the North Atlantic Oscillation (though with a southern centre of action shifted towards Europe).

The evolution of anomalies throughout the depth of the atmosphere can be investigated through the use of annular modes [e.g. *Baldwin and Dunkerton, 2001*].

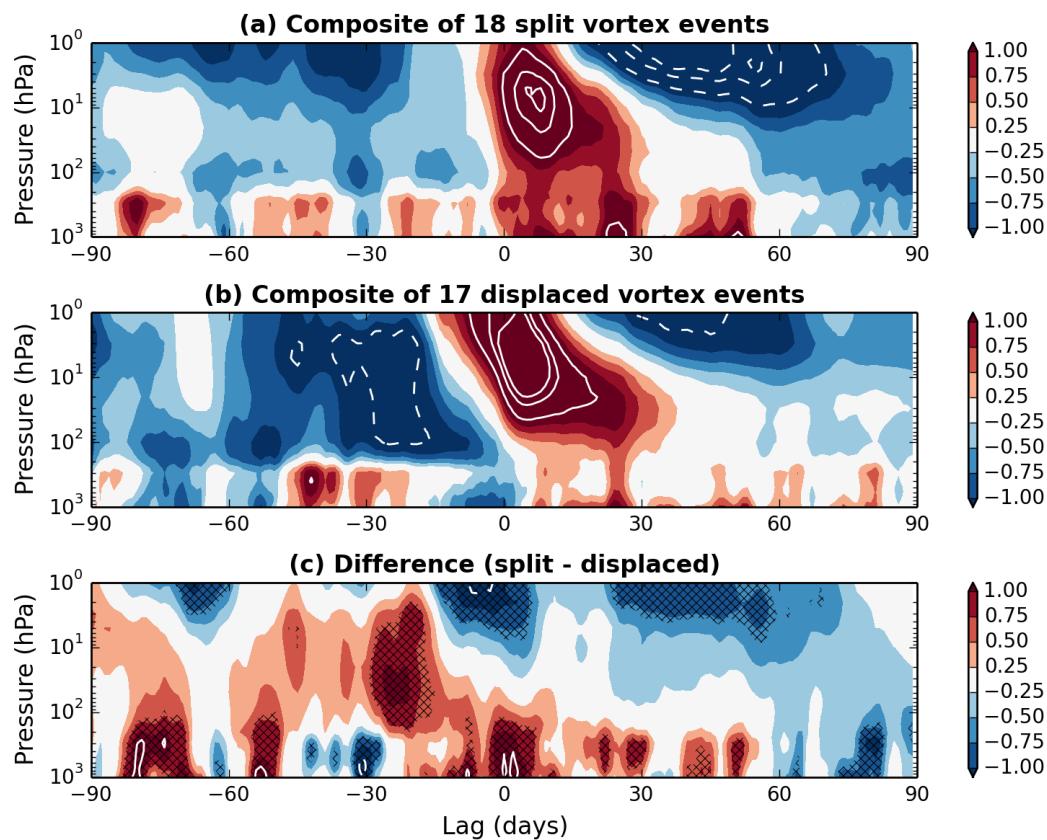

Figure 1.5: Composites of the time-height evolution of the NAM during (a) 17 vortex displacement events and (b) 18 splitting events. Lag 0 shows the onset of an event as measured at 10 hPa. Contour intervals are 0.25 and the region between -0.25 and 0.25 is unshaded. Data is from the ECMWF Reanalyses 1958-2009.

1.4. SUMMARY

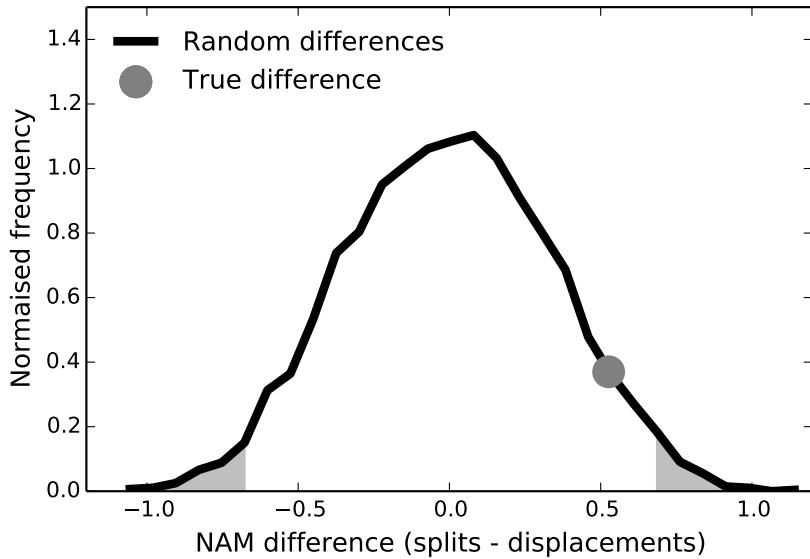

Figure 1.6: Distribution of 0-30 day mean NAM composite differences between split and displaced vortex events, formed by randomly shuffling the labels ‘split’ and ‘displacement’ between events. The 95% significant region (according to a two-tailed test) is shaded and the true composite difference is at the 94th percentile.

The Northern Annular Mode (NAM) (known as the Arctic Oscillation at the surface) is the leading mode of variability in the wintertime variability of the Northern Hemisphere circulation. Here we use the method of [Baldwin and Thompson, 2009], who define the NAM as the leading empirical orthogonal function (EOF) of daily wintertime (November-April) zonal mean geopotential height anomalies poleward of 20°N. The anomalies are calculated by subtracting the seasonal cycle which has been smoothed with a 90-day low-pass filter. The daily NAM anomalies are then determined by projecting daily geopotential anomalies onto the leading EOF patterns. Finally, the NAM is normalised at each level so that the entire time series has unit variance.

Figure ?? presents time-height composites of NAM anomalies 90 days either side of the onset date of displaced and split vortex events. Despite the larger stratospheric anomaly following displaced vortex events, the tropospheric signal is larger following split vortex events (as in Figure ??). The vertical evolution of these events also differs greatly, with anomalies descending from the upper stratosphere over a period of weeks for displacement events, while split vortex events are near barotropic. This suggests an excitation of the barotropic mode, which supports the idea of the wave resonance view of SSWs [Esler and Scott, 2005].

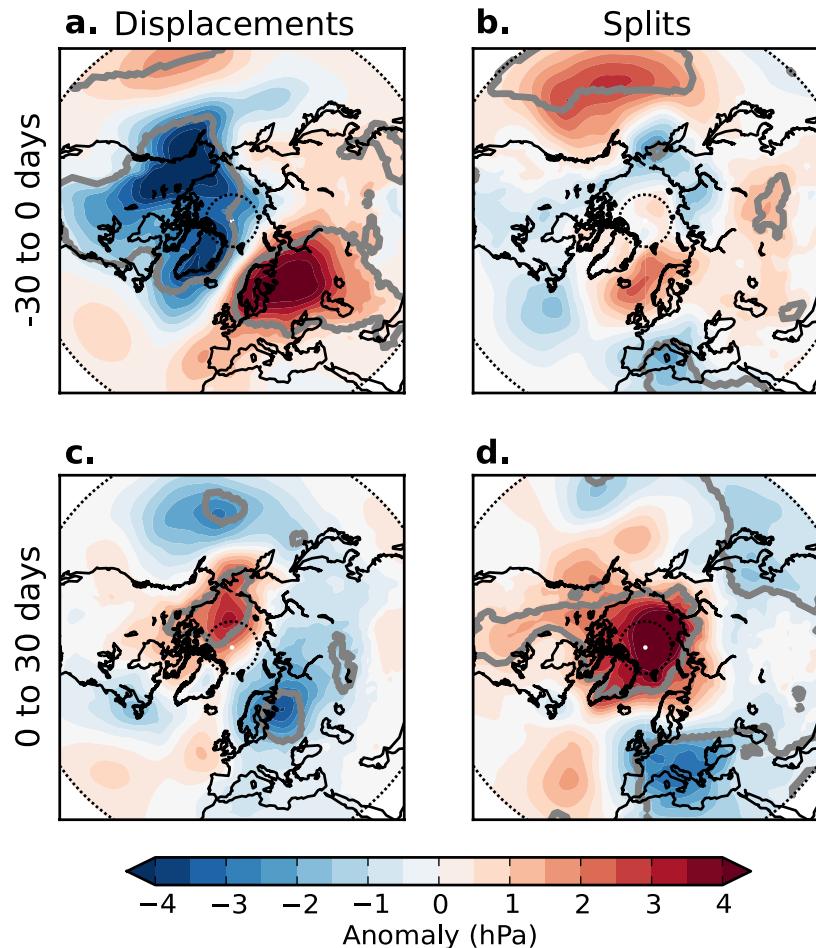

Figure 1.7: Composites of mean sea-level pressure anomalies in the 30 days before (a,b) and 30 days after (c,d) the onset dates of displaced (a,c) and split (b,d) vortex events from the Z_{10} method. Data is from the ECMWF reanalyses (1958–2009). Anomalies are calculated for each day and gridpoint from the climatology for that day of the year and gridpoint. Grey contours indicate regions of greater than 95% statistical significance according to a Monte-Carlo significance test.

1.4. SUMMARY

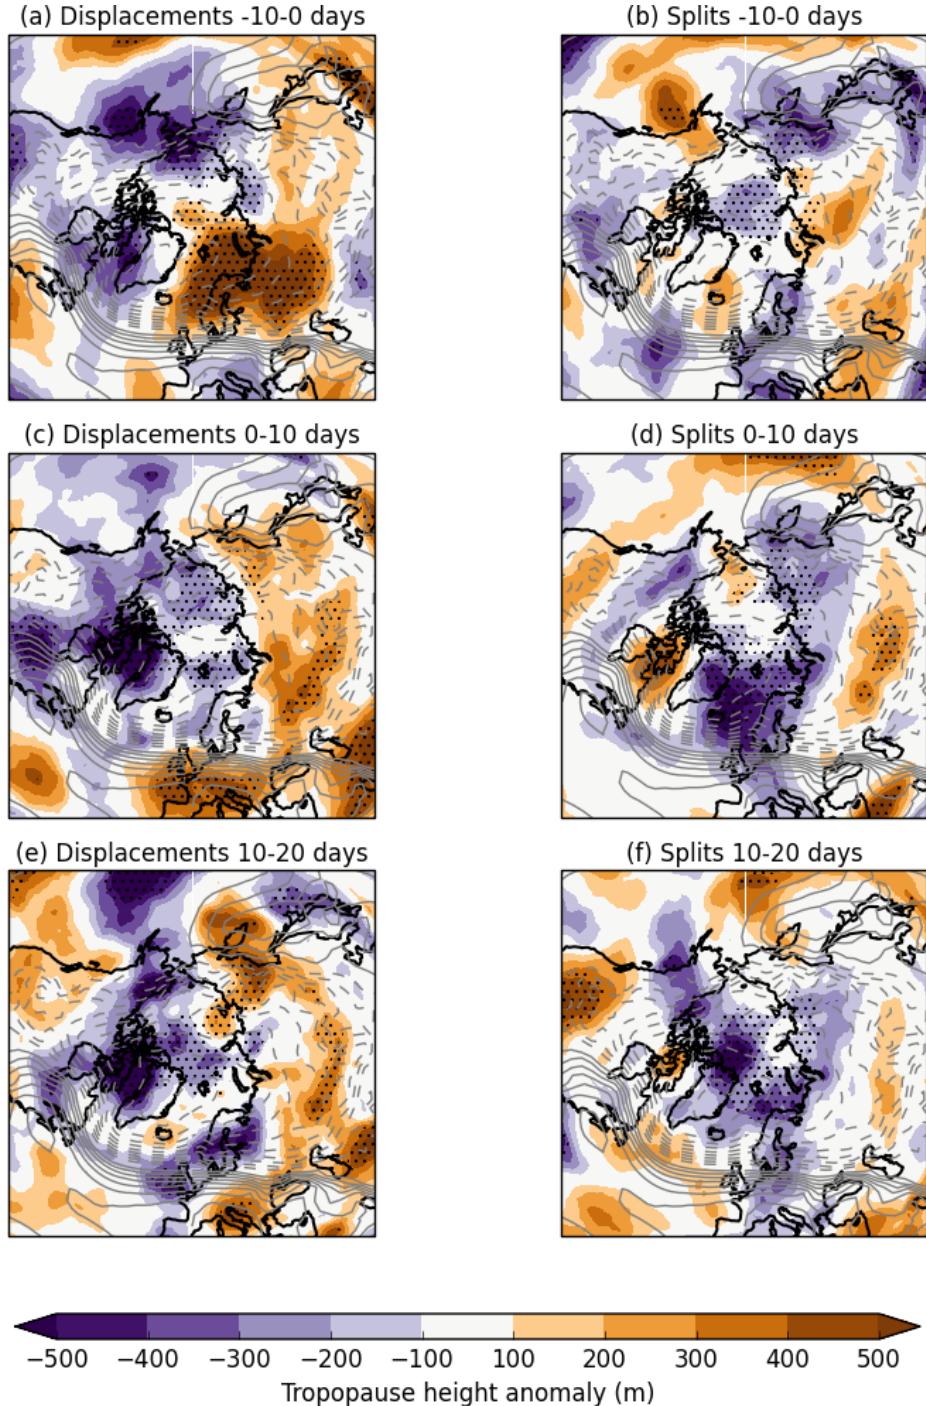

Figure 1.8: Composites of tropopause height anomalies averaged 10 days before (a,b), 10 days after (c,d) and 10-20 days after displaced and split vortex events. Anomalies are calculated for each day and gridpoint from the climatology for that day of the year and gridpoint. Stippling indicates regions of greater than 95% statistical significance according to a Monte-Carlo significance test. Grey contours indicate the first EOF of NH mean sea-level pressure, which explains 33% of the variance.

Overall, these results support the findings of M13, but use a new method to identify split and displaced vortex events, and extend the analysis to 2009. The fact that the results are consistent suggests the findings of M13 are robust and highlights the importance of distinguishing split and displaced vortex events in understanding stratosphere-troposphere coupling following SSWs.

CHAPTER 2

Representation of vortex variability in climate models

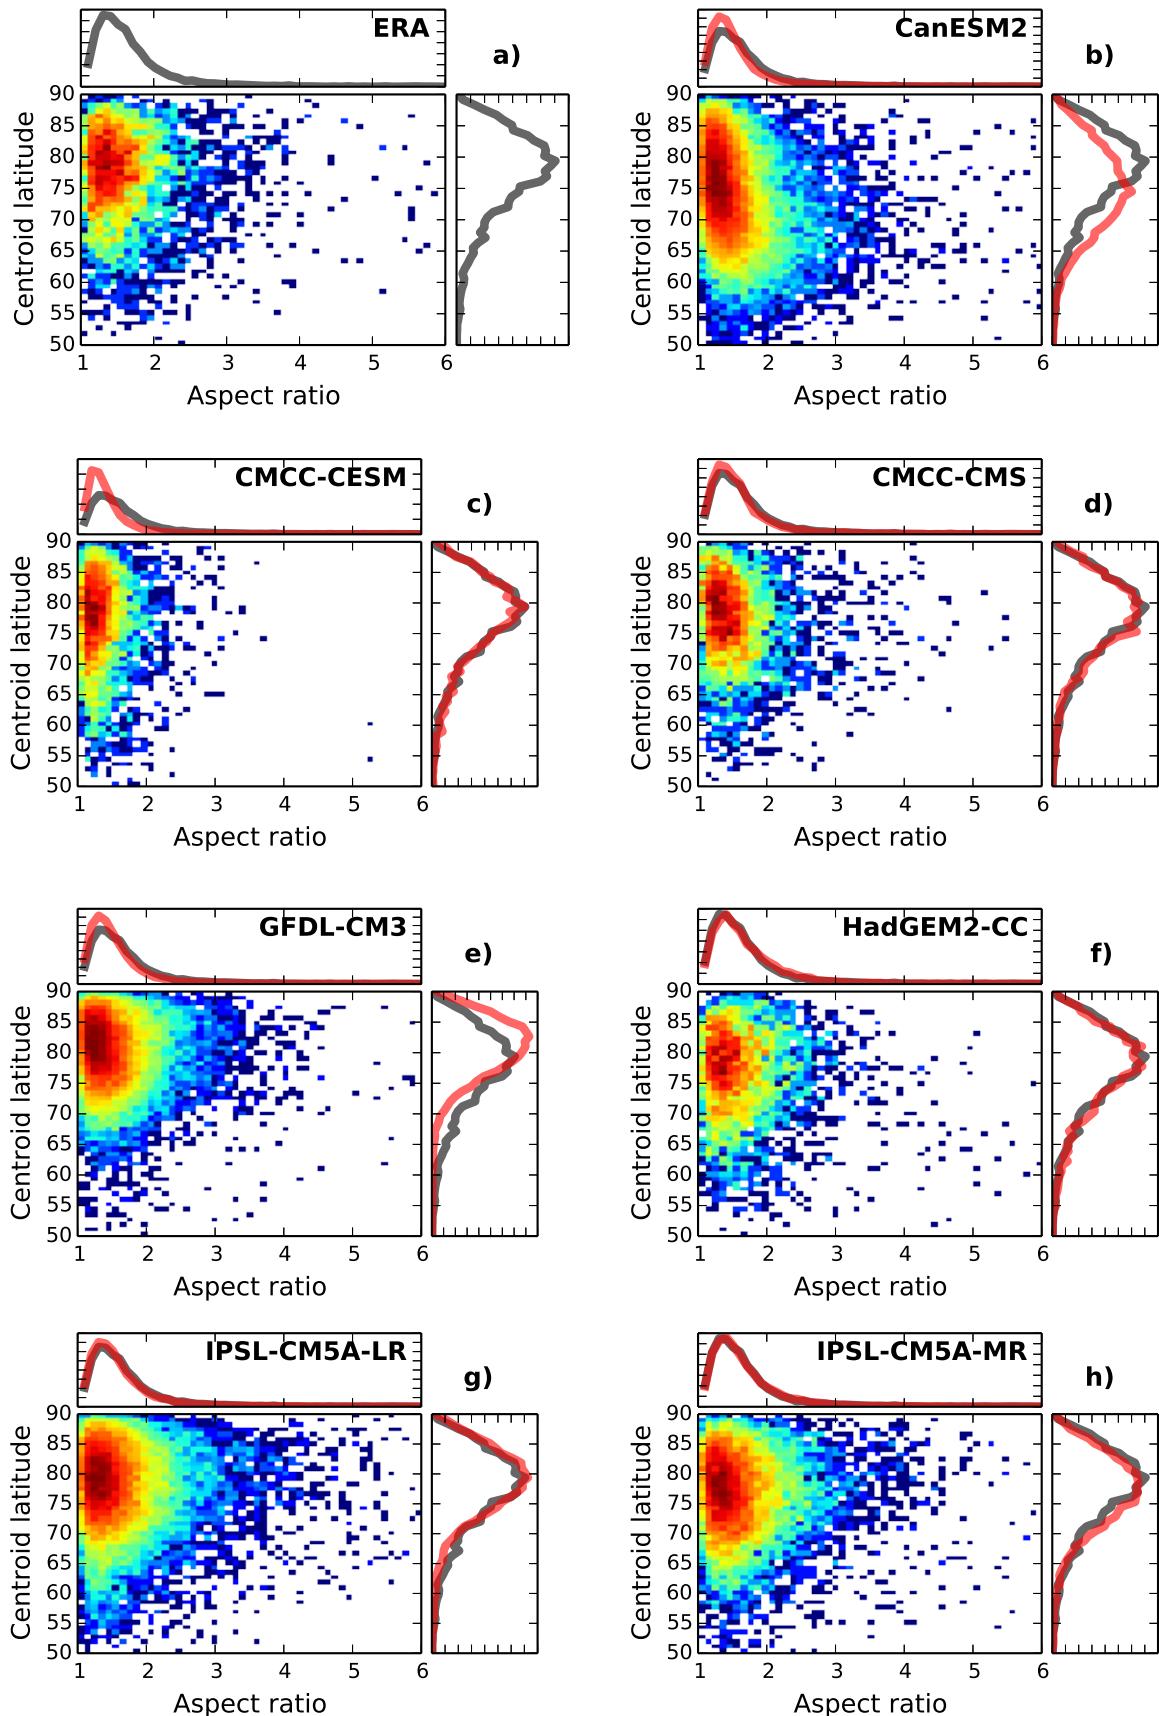

Figure 2.1: Distributions of centroid latitude and aspect ratio for the ERA (grey lines) (a) and the CMIP5 models (red lines). Joint distributions are shown with a logarithmic scale such that red squares represent the densest regions.

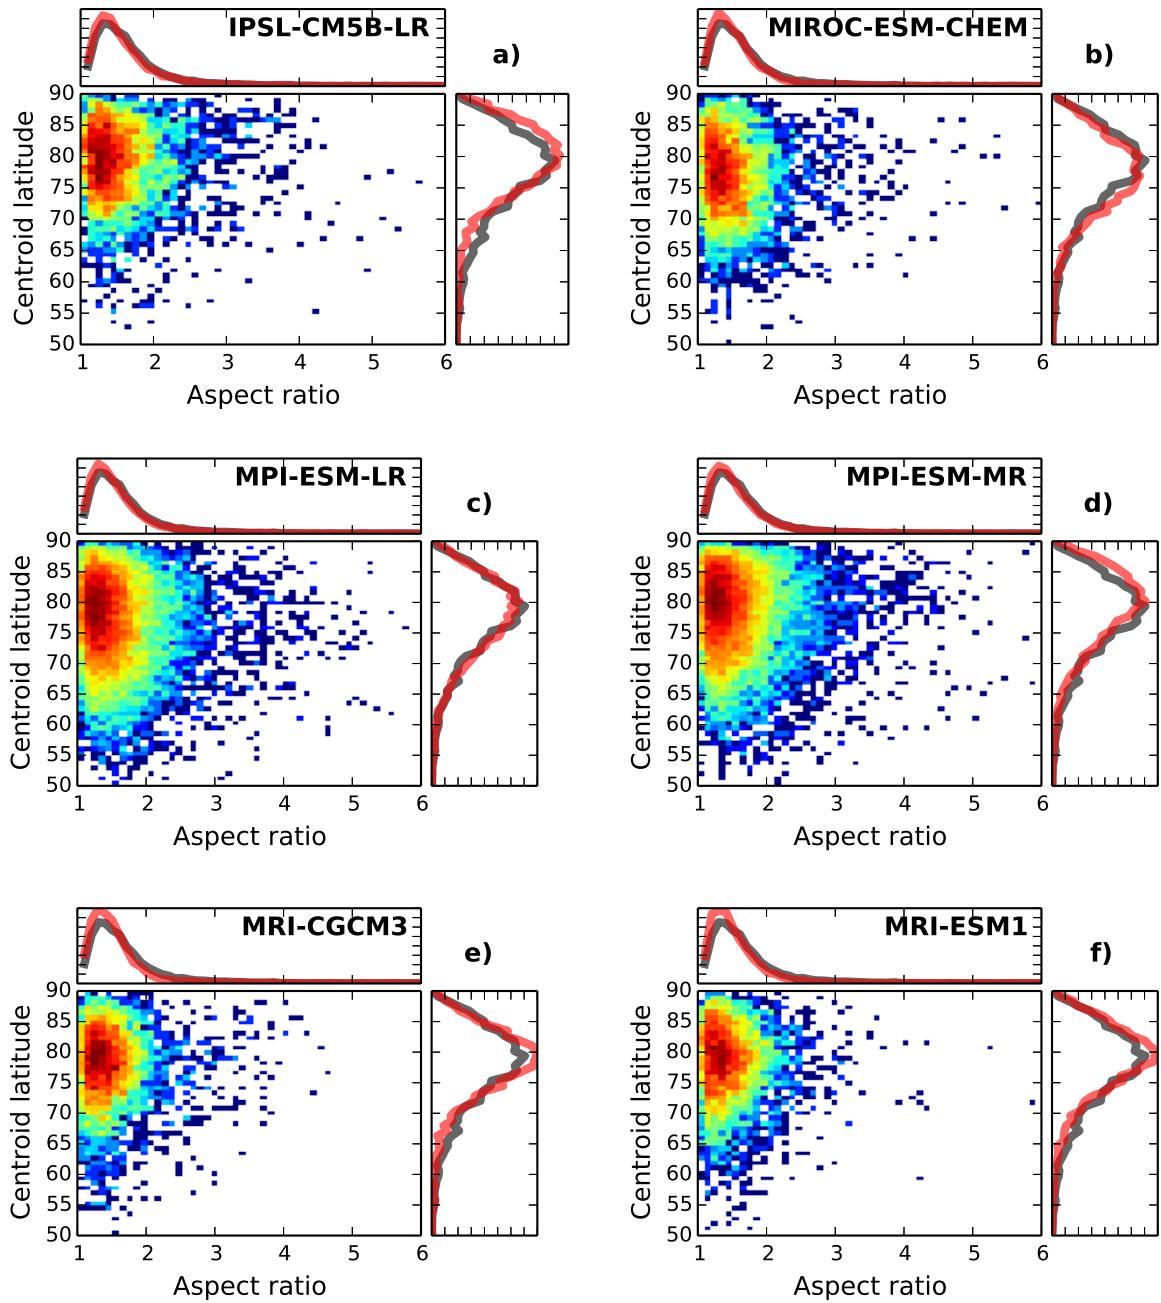

Figure 2.1: (Continued)

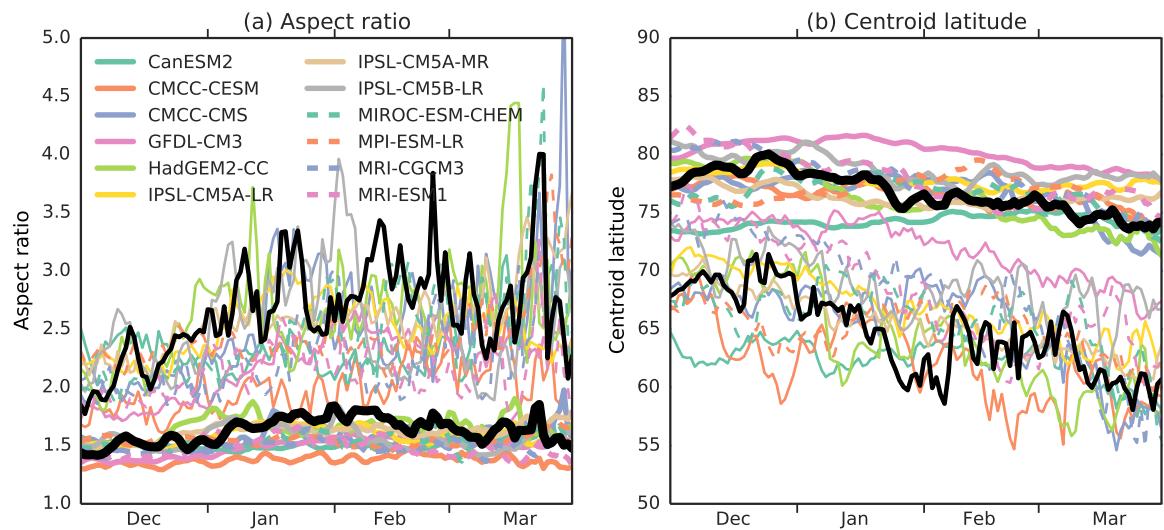

Figure 2.2: Seasonal cycle of aspect ratio and centroid latitude in ERA (black) and the CMIP5 models (colours). Thick lines represent the mean and thin lines the 95th or 5th percentile for aspect ratio and centroid latitude respectively.

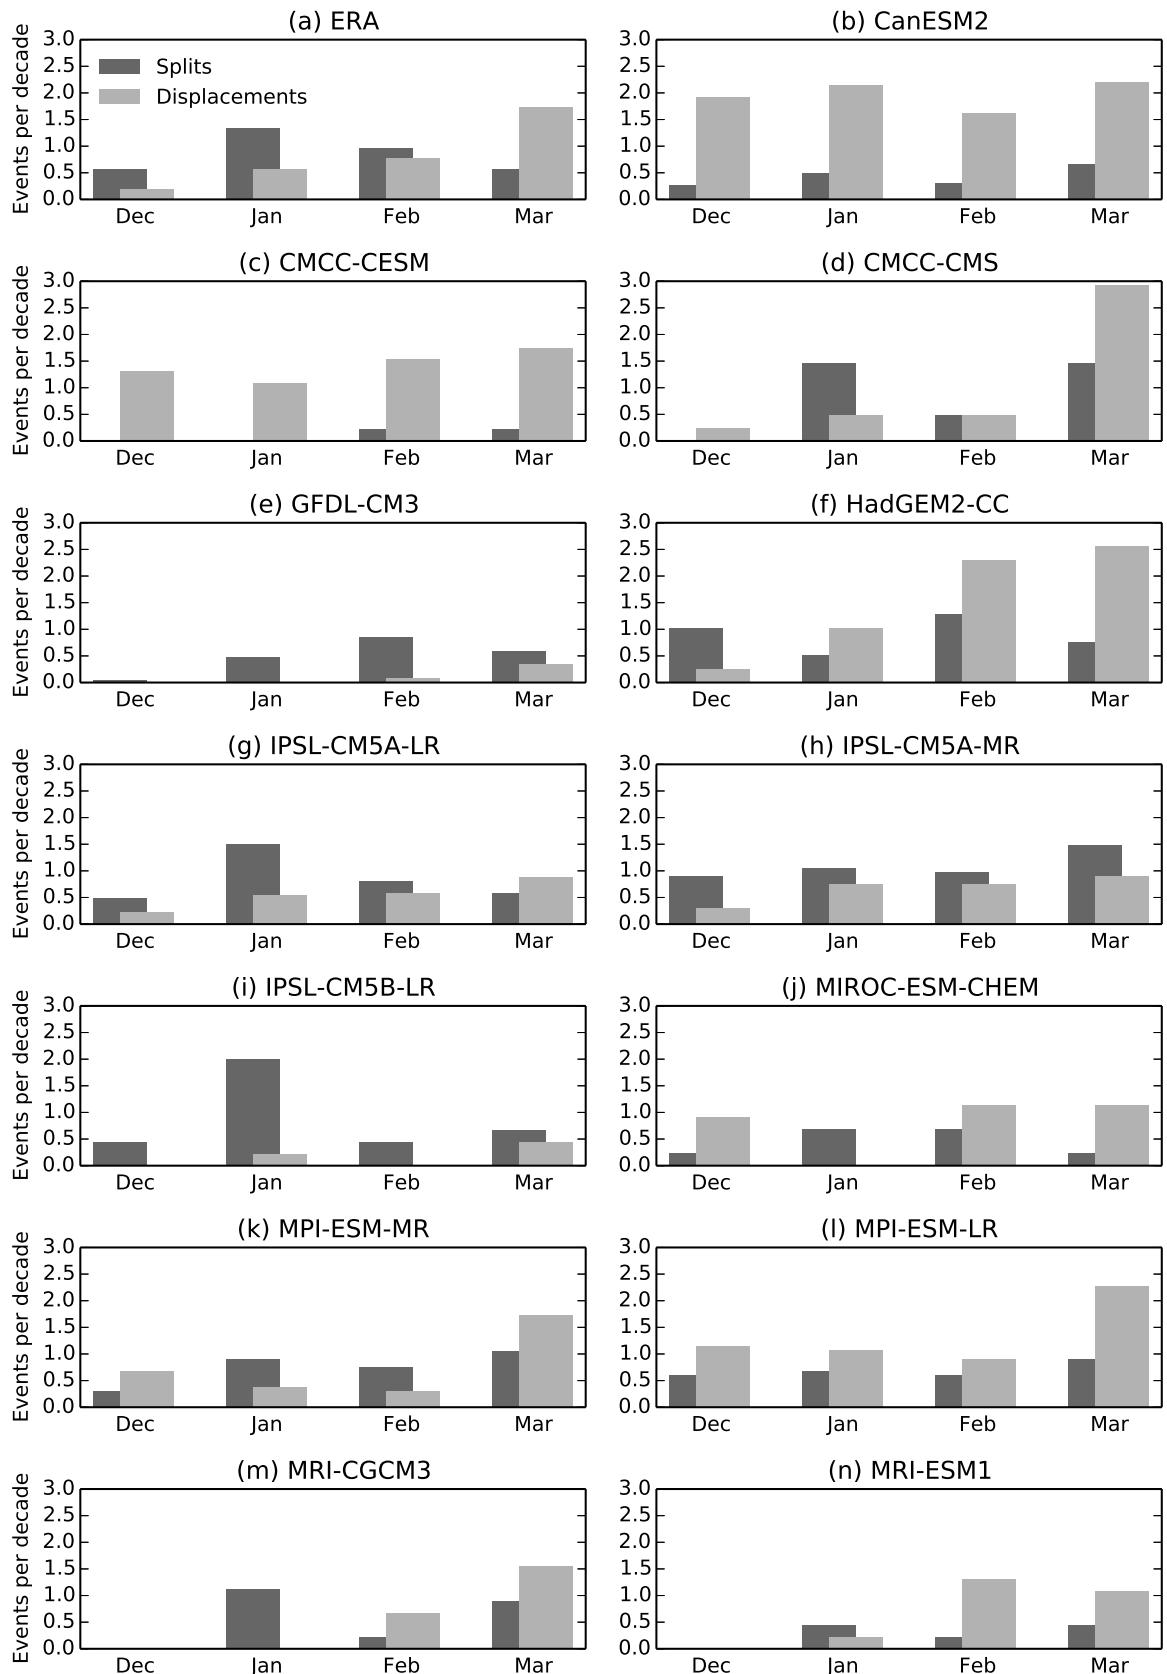

Figure 2.3: Seasonal distribution of the occurrence of split and displaced vortex events in ERA (a) and the CMIP5 models.

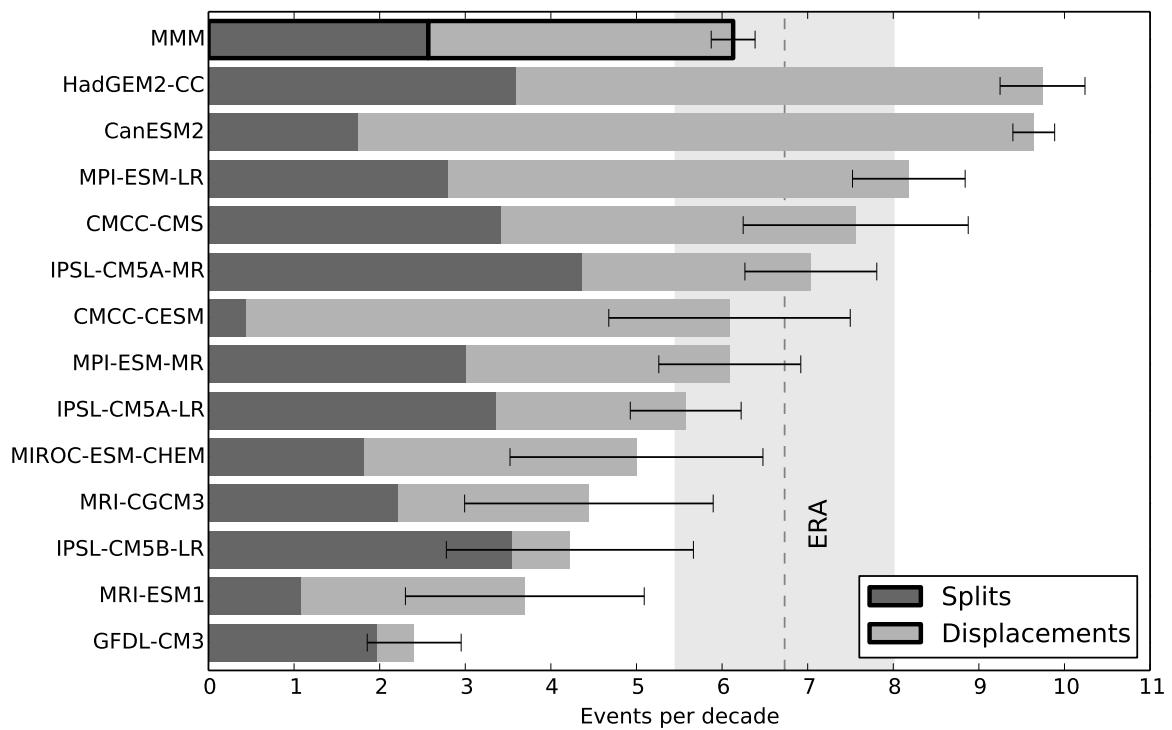

Figure 2.4: Frequency of split and displaced vortex events in the CMIP5 models. Error bars are for the frequency of all events, and represent one σ range, assuming a binomial distribution of events. The grey shaded region represents the one σ range for ERA, along with the mean (dashed line.)

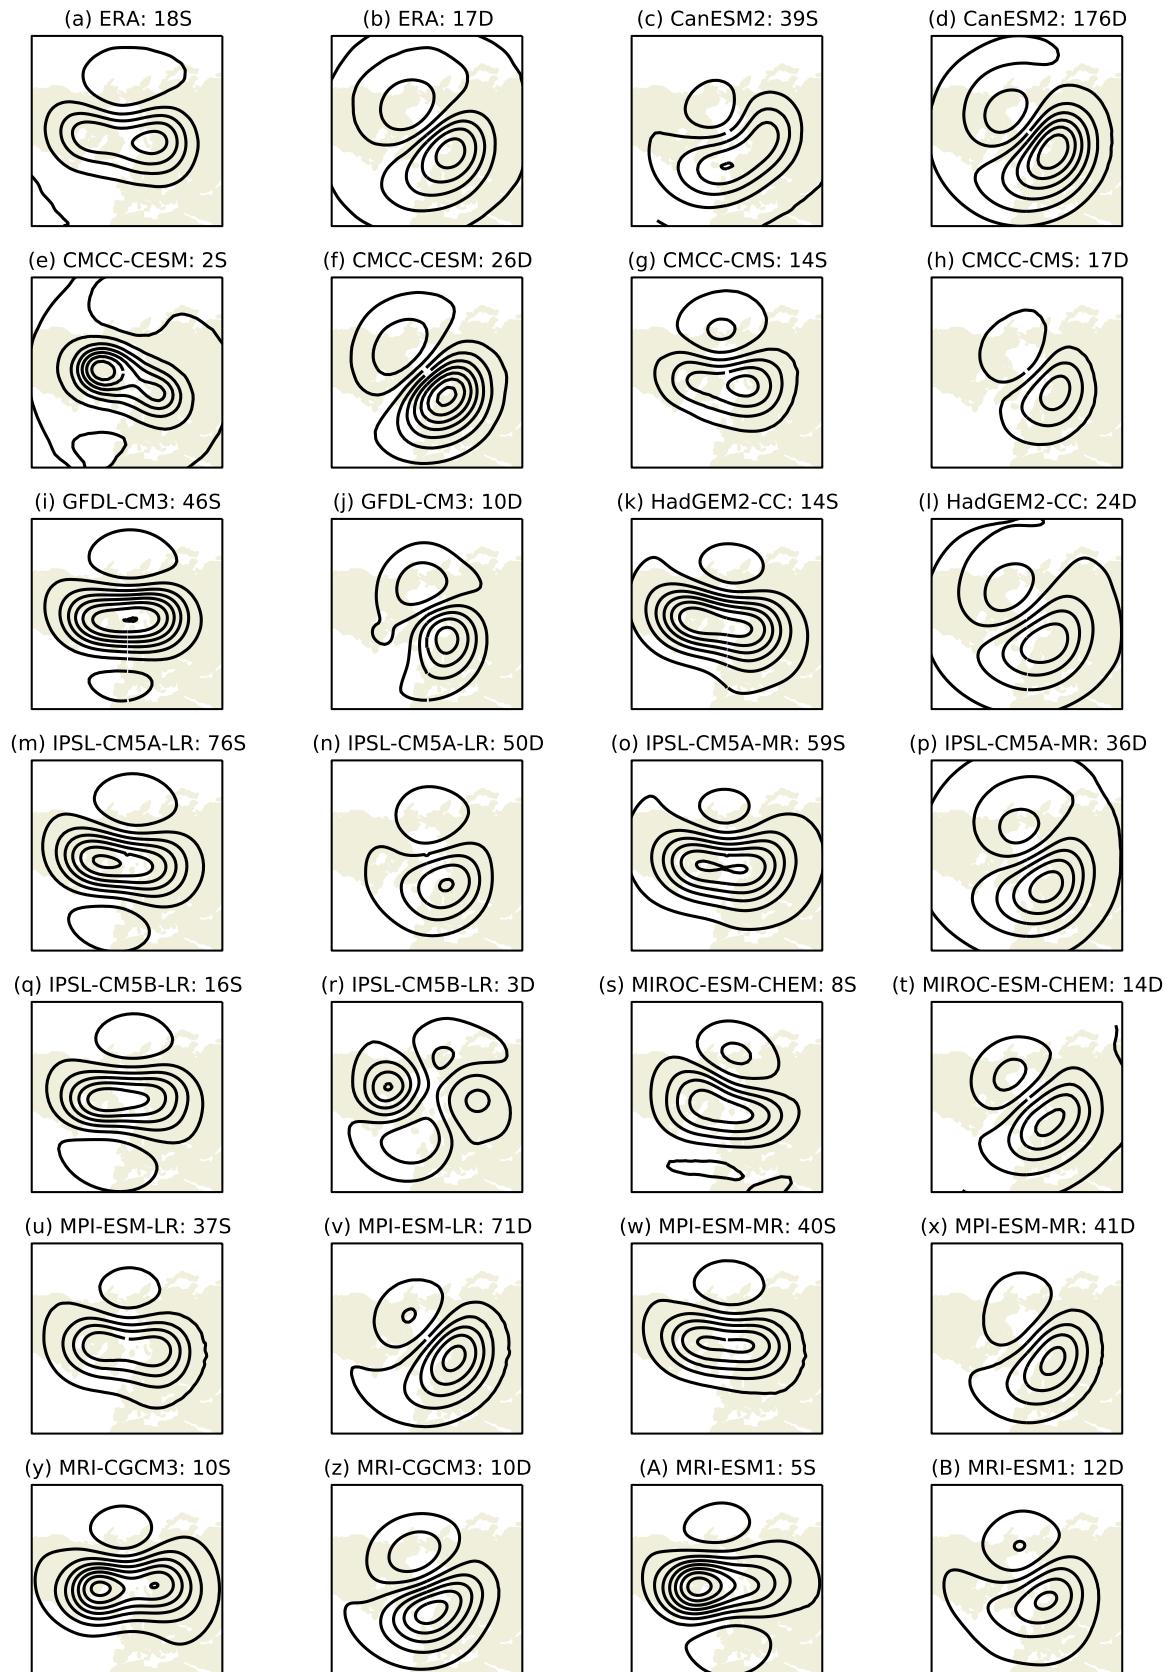

Figure 2.5: Composites of 10 hPa Zonal Wind at the onset date of split (S) and displaced (D) vortex events in ERA (a,b) and the CMIP5 models. The number of events entering the composite and their type are shown in the title of each plot. The contour interval is 0.3 km.

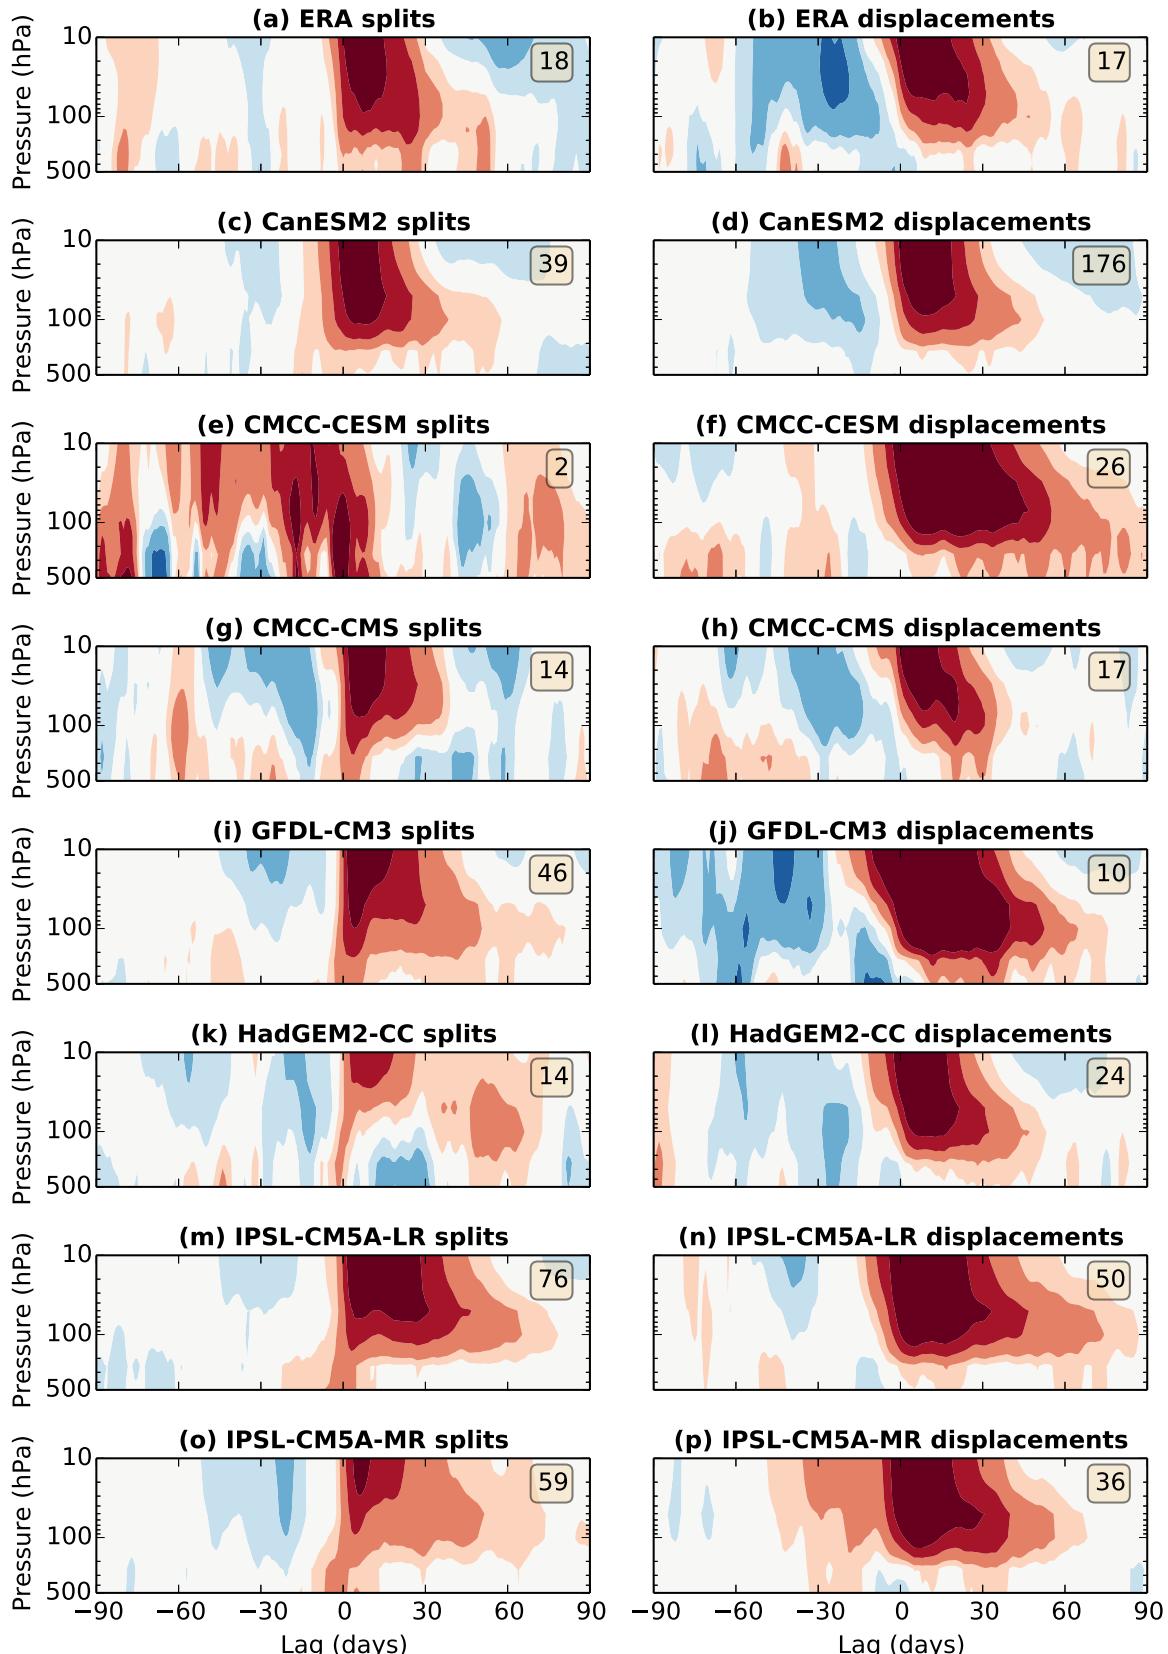

Figure 2.6: Composites of normalised polar cap averaged Z anomalies following split and displaced vortex events in ERA (a,b), the CMIP5 models, and the multi-model mean (C,D). Numbers in the upper right of each plot represent the number of events entering the composite.

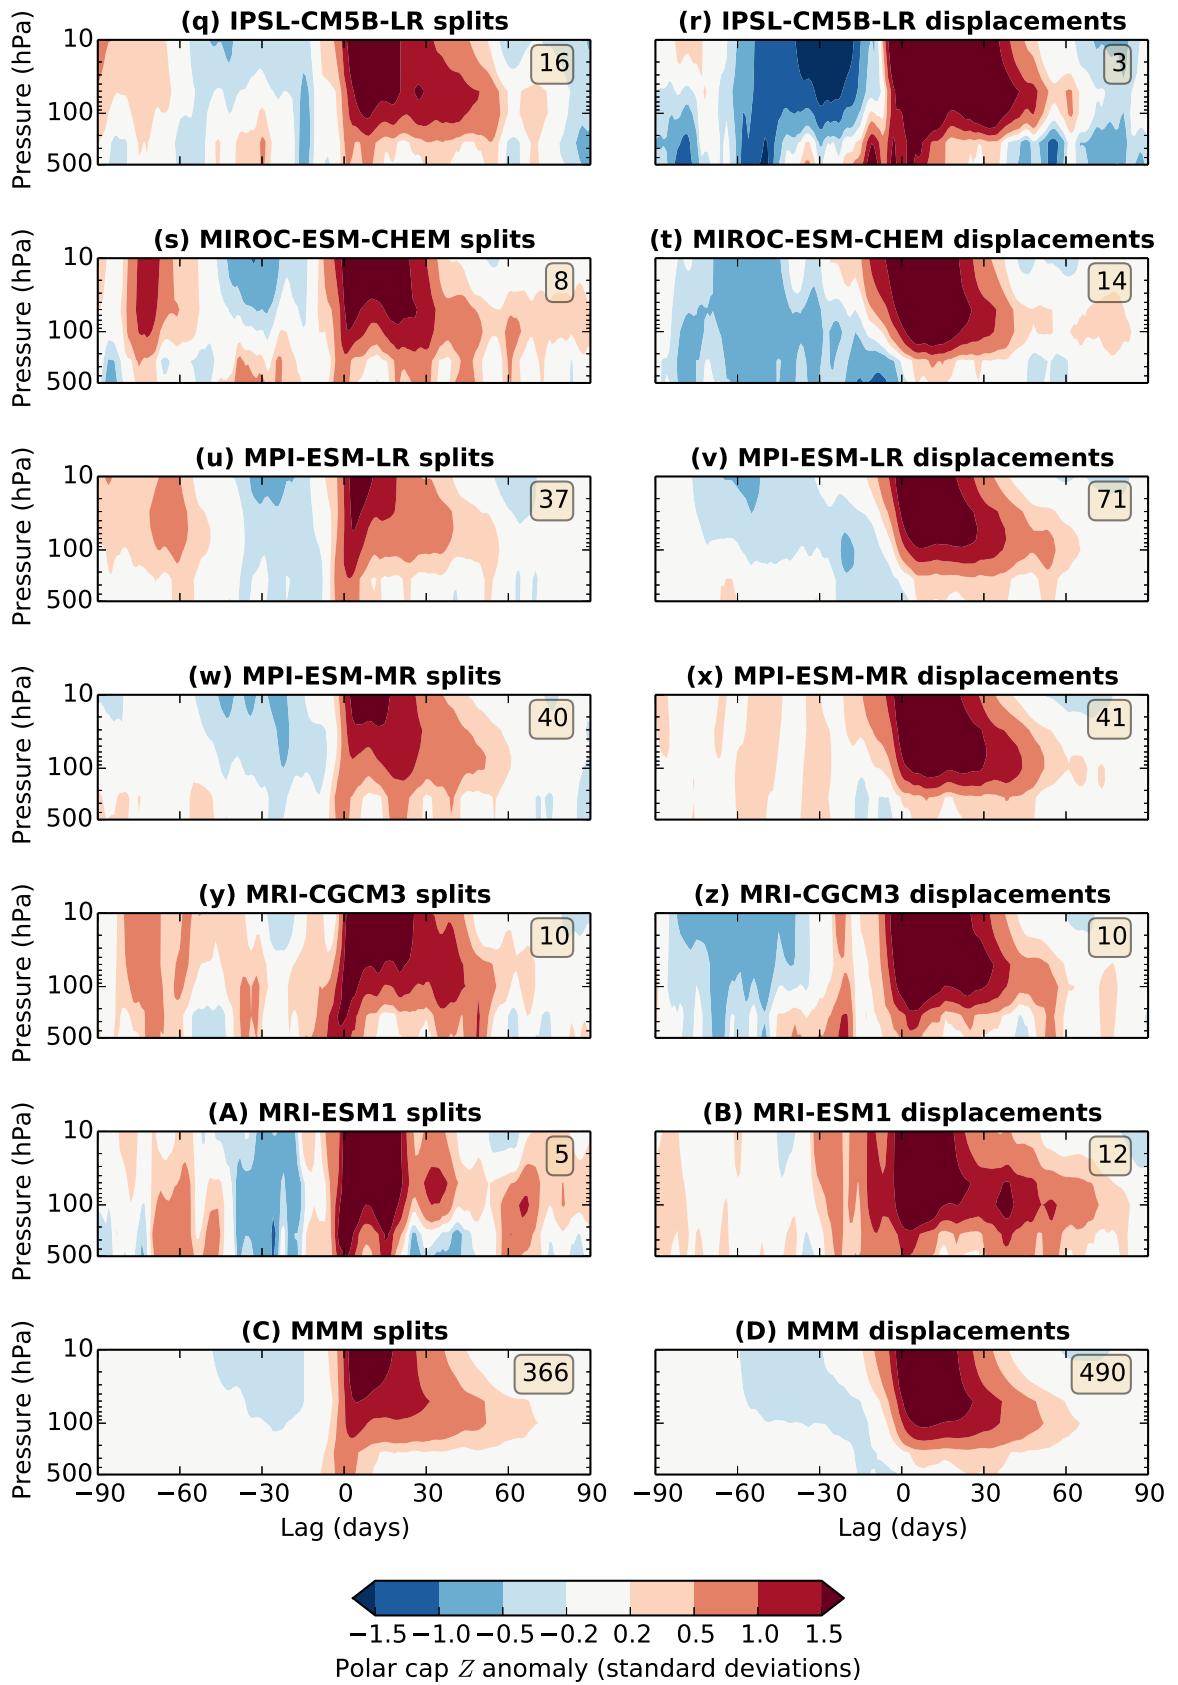

Figure 2.6: (Continued)

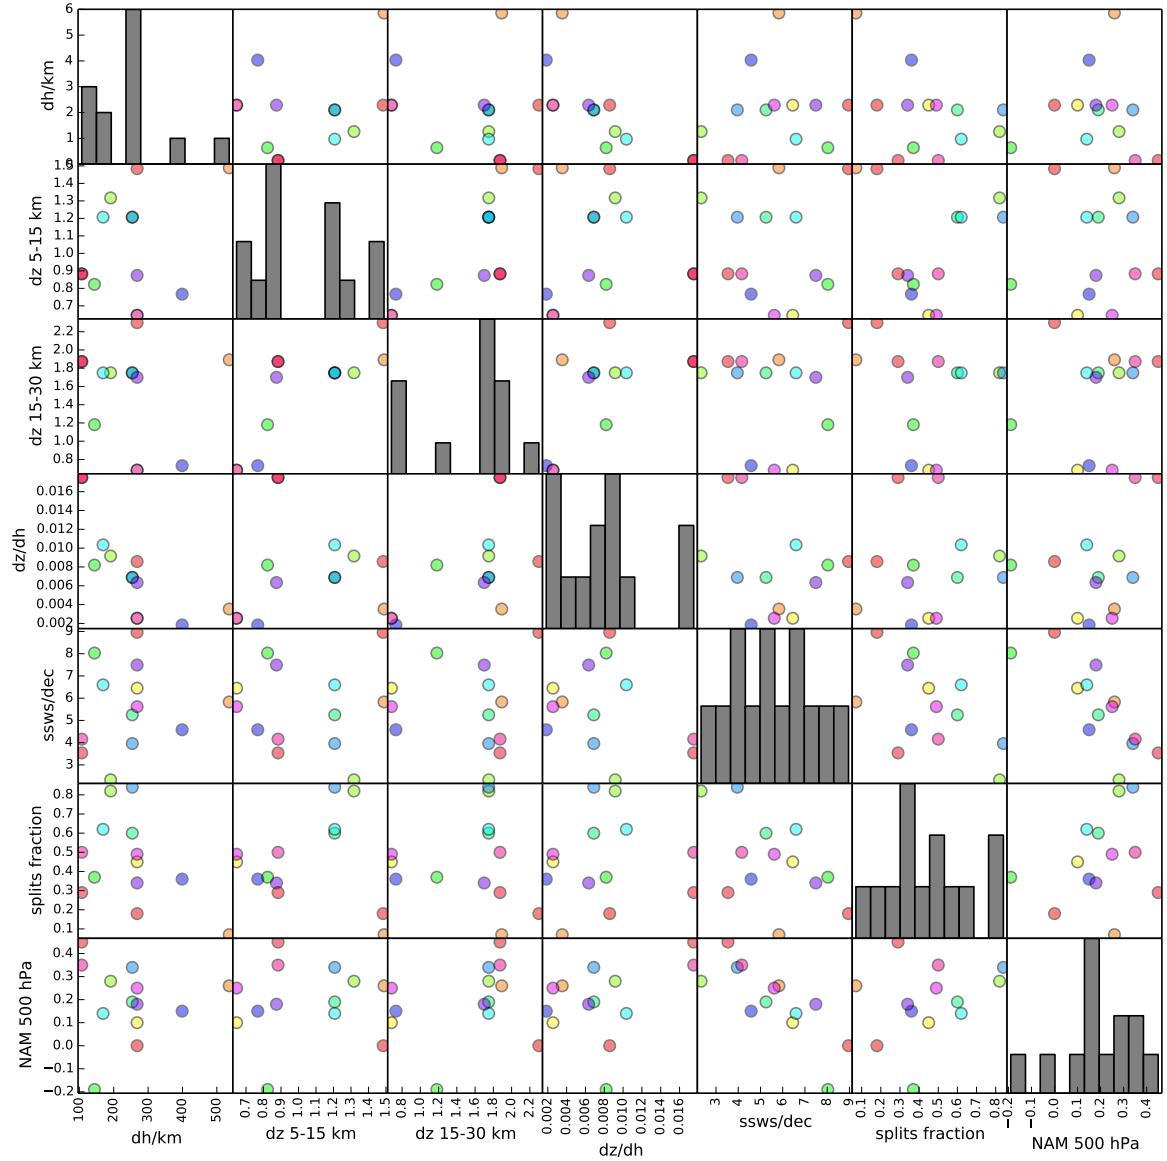

Figure 2.7: Relationship between model resolution and representation of split and displaced vortex events in the CMIP5 models. Model resolution is shown as horizontal resolution (dh), vertical resolution (dz) over 5-15 km and 15-30 km, and aspect ratio ($dz(5-15 \text{ km})/dh$). Also shown is the number of SSWs per decade, the fraction of SSWs that are splits, and the average NAM at 500 hPa 0-30 days following SSWs. Histograms for the relevant quantities are shown along the leading diagonal.

CHAPTER 3

The role of the stratosphere in seasonal prediction

3.1 Introduction

Accurate prediction of the atmospheric circulation several months in advance relies on the presence of low-frequency predictable signals in the climate system. It has now been demonstrated that the stratosphere is an important pathway for the communication of predictable tropical signals across the globe; in particular, the El Niño-Southern Oscillation (ENSO) [Pascoe *et al.*, 2006; Bell *et al.*, 2009; Ineson and Scaife, 2009; Hurwitz *et al.*, 2011], Quasi-Biennial Oscillation (QBO) [Marshall and Scaife, 2009; Garfinkel and Hartmann, 2011], and 11-year solar cycle [Kodera and Kuroda, 2002; Gray *et al.*, 2013]. These teleconnections allow for the possibility of significant predictability in regions remote from the direct effect of the signal. Despite this, many operational seasonal forecast models include only a poor representation of the stratosphere [Maycock *et al.*, 2011], and it has been suggested that this contributes to their lack of seasonal forecast skill in the extratropics [Smith *et al.*, 2012].

Furthermore, because stratospheric anomalies persist for longer than those in the troposphere and can influence surface weather patterns [e.g., Baldwin and Dunkerton, 2001], the initial conditions of the stratosphere itself can act as a source of enhanced predictability [Baldwin *et al.*, 2003; Charlton *et al.*, 2003; Hardiman *et al.*, 2011]. The effect of the stratosphere on the troposphere is most pronounced following a rapid midwinter breakdown of the strong westerly stratospheric polar vortex (known as a stratospheric sudden warming, SSW), and past work has fo-

cused on the influence of these events on forecast skill [*Kuroda*, 2008; *Sigmond et al.*, 2013]. However, SSWs are highly nonlinear events which are currently not predictable beyond about two weeks in advance [*Marshall and Scaife*, 2010], limiting their usefulness in seasonal prediction. SSWs also occur almost exclusively in the Northern Hemisphere (NH), with only one event in the approximately 60 year record having been observed in the Southern Hemisphere (SH), in September 2002 [*Roscoe et al.*, 2005].

The rarity of SSWs in the SH is a result of less dynamical forcing from vertically propagating planetary waves in the SH relative to the NH stratosphere. This, in turn, comes about because of lesser SH orography and land-sea temperature contrasts which can excite planetary waves. This reduced variability also means that anomalies in the Antarctic stratosphere persist for longer than those in the Arctic [*Simpson et al.*, 2011], so they may be predictable on longer time scales, and so more useful for seasonal forecasts, despite the lack of SSWs. Indeed, *Thompson et al.* [2005] and *Son et al.* [2013] have found that smaller-amplitude variations in the Antarctic stratospheric polar vortex are followed by coherent temperature and pressure anomalies at the Earth's surface which resemble the Southern Annular Mode (SAM) pattern. These observations led *Roff et al.* [2011] to find that improved forecasts of the SAM up to 30 days ahead may be achieved with a stratosphere-resolving model. The SAM is the dominant mode of variability of the extratropical Southern Hemisphere and affects the position of storm tracks, rainfall, surface air temperature, and ocean temperatures across the extratropics [e.g., *Silvestri and Vera*, 2003; *Reason and Rouault*, 2005; *Hendon et al.*, 2007]. As such, there are considerable societal benefits, and interests in its prediction [*Lim et al.*, 2013].

Another reason for interest in the prediction of the Antarctic stratosphere is the interannual variability in springtime ozone depletion. The magnitude of this interannual variability is a significant fraction of the magnitude of long-term depletion caused by emission of chlorofluorocarbons (CFCs) and other ozone-depleting substances. While ozone-depleted air is confined over the polar region by the stratospheric polar vortex during winter and spring (resulting in the ozone hole), following the ultimate breakdown of the vortex (final warming) in late spring/early summer, this air becomes released to mid-latitudes. The extent of this summertime ozone depletion is largely determined by the total deficit in ozone over the Antarctic during spring [*Bodeker et al.*, 2005]. Interannual variability in springtime ozone depletion can therefore significantly affect the amount of

3.1. INTRODUCTION

harmful ultraviolet radiation reaching the Earth's surface over more populated areas of the Southern Hemisphere.

Salby et al. [2012] have shown that interannual variations in Antarctic ozone depletion are highly correlated with changes in planetary wave forcing of the stratosphere. They found that the anomalous vertical Eliassen-Palm (EP) flux (a measure of the momentum transmitted by planetary waves) entering the stratosphere poleward of 40°S during August–September explains almost all the interannual variance of anomalous ozone depletion during September–November. Using this relationship, they postulate that accurate prediction of planetary wave forcing could allow skillful seasonal forecasts of ozone depletion.

The influence of planetary wave forcing on ozone depletion comes about through both chemical and dynamical mechanisms. Planetary wave breaking causes an increase of the strength of the stratospheric residual mean meridional circulation [*Haynes et al.*, 1991], with a resultant increase in large-scale descent and adiabatic warming over the pole. This warming inhibits the formation of polar stratospheric clouds which have a vital role in the activation of halogen species that cause the chemical depletion of ozone. The increased meridional circulation as well as an enhancement of horizontal two-way mixing caused by planetary wave breaking, also cause an increase in the dynamical transport of tropical ozone-rich air to the polar regions, further increasing ozone concentrations. Breaking planetary waves can also modify the geometry of the stratospheric polar vortex, stripping away elements of ozone-depleted air [*Waugh et al.*, 1994], or in the extreme case of the 2002 SSW cause the ozone hole to split in two [*Charlton et al.*, 2005].

Here, we address directly the influence of the stratosphere on springtime Antarctic seasonal forecast skill using a set of historical hindcasts (or historical re-forecasts) of a new operational system with a fully stratosphere-resolving general circulation model. We find significant skill in the prediction of the Antarctic stratospheric polar vortex up to four months in advance, and even of the 2002 SSW. Using the observed relationship between column ozone quantities and the stratospheric circulation, we are then able to infer skillful predictions of springtime ozone depletion, confirming the hypothesis of *Salby et al.* [2012]. This exceeds the lead-time of other contemporary ozone forecasts, which are typically no more than two weeks (Eskes 2005). The forecast system also shows highly significant levels of skill in the prediction of the surface SAM at seasonal lead times. By studying the variation of hindcast skill with time and height, we demonstrate

that this skill is significantly influenced by the descent of long-lived stratospheric circulation anomalies.

3.2 Seasonal forecast system

The analysis in this paper is based on results from a set of hindcast predictions produced by the Met Office Global Seasonal Forecast System 5 (GloSea5) [MacLachlan *et al.*, 2014]. This system is based upon the HadGEM3 coupled general circulation model [Hewitt *et al.*, 2011], with an atmospheric resolution of 0.83° longitude by 0.56° latitude, 85 quasi-horizontal atmospheric levels and an upper boundary at 85 km. The ocean resolution is 0.25° in longitude and latitude, with 75 quasi-horizontal levels. A 15-member ensemble of hindcasts was run for each year in the period 1996–2009. The hindcast length is approximately four months from three separate start dates spaced two weeks apart and centered on 1st August (07/25, 08/01, 08/09), with 5 members initialised on each start date. Members initialised on the same start date differ only by stochastic parameterization of model physics [Tennant *et al.*, 2011].

Initial conditions for the atmosphere and land surface were taken from the ERA-Interim reanalysis [Dee *et al.*, 2011], and initial ocean and sea-ice concentrations from the GloSea5 Ocean and Sea Ice Analysis, based on the FOAM data assimilation system [Blockley *et al.*, 2013]. Beyond initialisation the model takes no further observational data, and contains no flux corrections or relaxations to climatology. The model lacks interactive chemistry, and ozone concentrations are fixed to observed climatological values averaged over 1994–2005, including a seasonal cycle [Cionni *et al.*, 2011].

Scaife et al. [2014] have shown that this seasonal forecast system produces unprecedented skillful forecasts of the North Atlantic Oscillation during the Northern Hemisphere winter. The combined effects of ENSO, QBO and sea-ice teleconnections, as well as to the increased ocean resolution, which has improved the representation of Northern Hemisphere blocking events [*Scaife et al.*, 2011] contribute to this skill.

Hindcast accuracy is verified by comparison to the ERA-Interim reanalysis [Dee *et al.*, 2011]. This provides a ‘clean comparison’ since the hindcasts exactly match ERA-Interim at the initialisation date. The ERA-Interim data set has been demonstrated to have realistic representation of the stratospheric meridional circulation [Seviour *et al.*, 2012; Monge-Sanz *et al.*, 2013]. It also assimilates observa-

3.3. SEASONAL FORECAST RESULTS

tions of ozone concentrations, and this assimilation has been demonstrated to be in close agreement with independent satellite data [*Dragani, 2011*].

3.3 Seasonal forecast results

3.3.1 Stratospheric polar vortex

The climatology of Antarctic stratospheric polar vortex winds in the GloSea5 hindcasts is compared to the ERA-Interim reanalysis climatology in Fig. 3.1. The strength of the stratospheric polar vortex is measured by the zonal-mean zonal wind (\bar{U}) at 60°S and 10 hPa, which is approximately the center of the mean position of the vortex in the mid-stratosphere. The composite for the GloSea5 hindcasts is formed from all the individual ensemble members over 1996–2009 (a total of 210 realizations), while that from ERA-Interim is a composite of all years from 1979–2010 (a total of 32 years). It can be seen that the mean of the GloSea5 hindcasts agrees very closely with ERA-Interim throughout the spring, with only a slight bias towards weaker winds in August and September. The interquartile and 95th percentile ranges of GloSea5 and ERA-Interim also agree well, although the ERA-Interim values are noisier as would be expected from a sample size consisting of fewer years.

The GloSea5 hindcast skill for the prediction of the Antarctic stratospheric polar vortex winds is shown in Fig. 3.2(a). Anomalies are defined from the relevant climatology of either GloSea5 or ERA-Interim. For GloSea5, this climatology is calculated from the mean of each day across all ensemble members in all years, while for ERA-Interim the climatology is the mean of each day, smoothed with a 30-day running mean (in order to account for its increased noise due to the fact it consists of only a single realization). Results are shown for September–November (SON) averages, corresponding to a 1–4 month lead time. The correlation between the GloSea5 ensemble mean and ERA-Interim is 0.73, which is statistically significant at the 99% confidence level. This correlation does not depend strongly on particular years; the correlation remains significant at the 95% level ($r = 0.57$) if the year 2002 is excluded. Significance is calculated using a two-tailed bootstrap test, whereby the percentile of the observed correlation is calculated from a distribution formed by the correlation of a large number ($\sim 10,000$) of pairs of time series formed by re-sampling with replacement from the original time series. These significance tests make fewer assumptions about the underlying structure of the data than parametric tests [*Wilks, 2006*], and are used throughout this study.

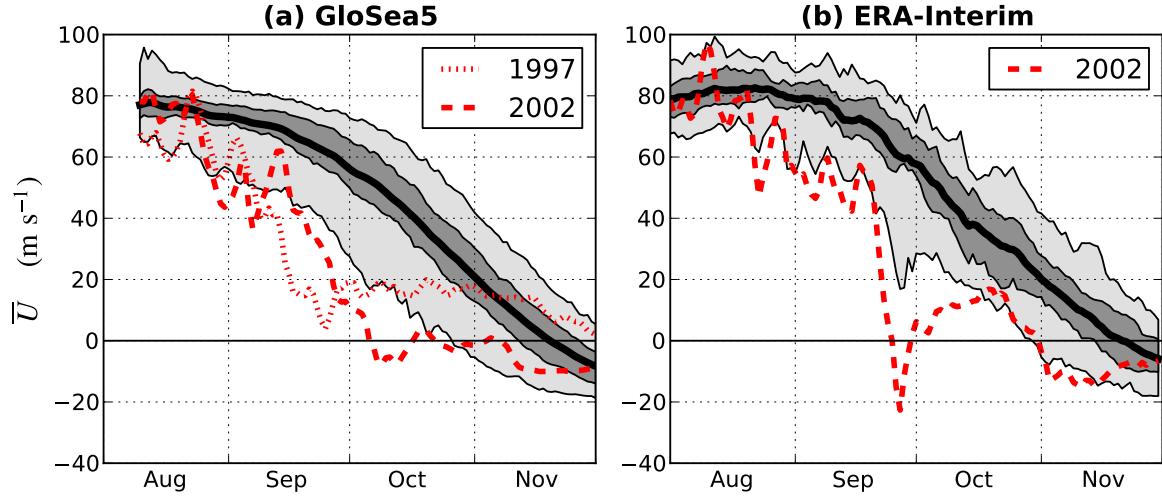

Figure 3.1: Time series of daily 10 hPa zonal-mean zonal wind (\bar{U}) at 60°S for all GloSea5 ensemble members from 1996–2009 (a) and ERA-Interim from 1979–2010 (b). The thick black line indicates the mean, dark grey shading the interquartile range and light grey the 95th percentile range. Individual time series of the two ensemble members of GloSea5 which simulate an SSW (one for 1997 and one for 2002), and the year with an observed SSW (2002) are shown in red.

Two SSW events were simulated in the GloSea5 hindcasts; in 1997 and 2002. Time series of stratospheric polar vortex winds for these events are shown in Fig. 3.1(a) along with the observed 2002 SSW in Fig. 3.1(b). Note that although \bar{U} at 60°S and 10 hPa does not quite become easterly for the 1997 event, it does become easterly *poleward* of 60°S , which satisfies the World Meteorological Organization definition of a SSW. Given the total of 210 ensemble hindcasts, these two simulated events suggest a frequency of Southern Hemisphere SSW events of approximately one in 100 years in the current climate (making the assumption that the model can accurately simulate the probability of these events). It can also be seen that 2002 has the most anomalous stratospheric polar vortex in the GloSea5 hindcasts, with 14 of 15 ensemble members simulating negative anomalies, and the most negative ensemble mean. It is therefore possible that the 2002 event was to some degree predictable about two months in advance, although it has not been determined whether this predictability comes from a preconditioning of the vortex, as suggested by [Scaife et al. \[2005\]](#), or the result of external forcing.

It should be noted that both the SSW events simulated by GloSea5 were vortex displacement events, in contrast to the vortex splitting event which occurred in 2002 [[Charlton et al., 2005](#)]. This is demonstrated in Fig. 3.3, which shows geopotential height in the mid-stratosphere at the central date (date of minimum at \bar{U}

3.3. SEASONAL FORECAST RESULTS

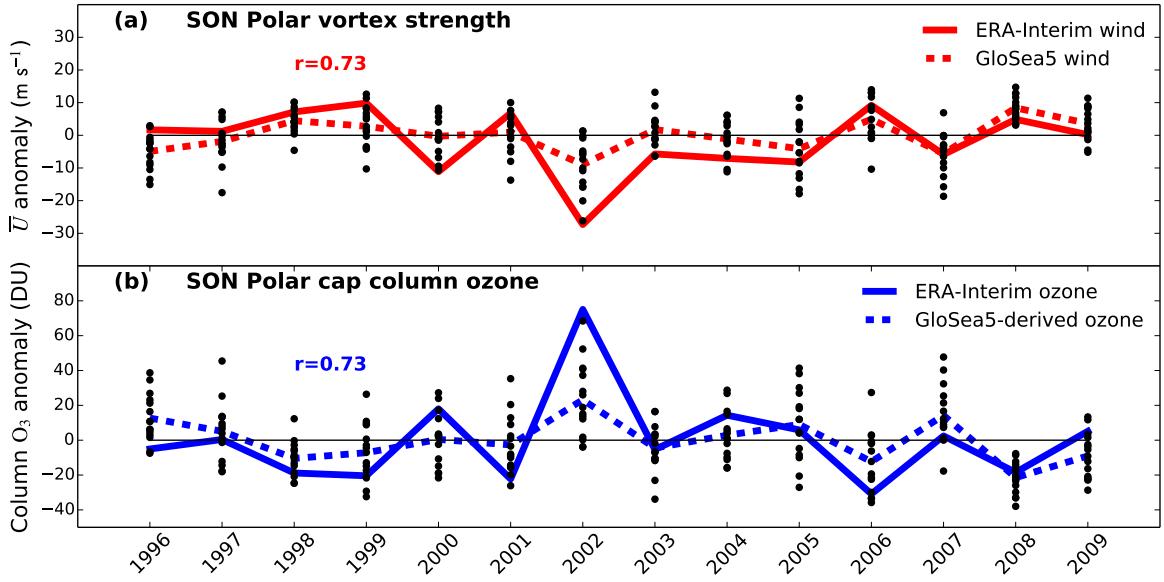

Figure 3.2: (a) SON mean anomalies at 10 hPa and 60°S in ERA-Interim and the GloSea5 hindcast ensemble mean. (b) SON mean polar cap averaged (60–90°S) total column ozone anomalies from ERA-Interim and those derived from the GloSea5 anomalies as described in the text. Individual ensemble members are shown as black dots. Hindcasts are initialised near 1st August.

60°S and 10 hPa) of the two simulated events in GloSea5 and the observed event in ERA-Interim. The distinction between splitting and displacement SSW events is important because it has been observed that tropospheric anomalies are greater following vortex splitting events, at least in the Northern Hemisphere [Nakagawa and Yamazaki, 2006; Mitchell et al., 2013].

The timing of the final warming of the stratospheric polar vortex has a significant effect on stratospheric temperature and ozone concentrations [Yamazaki, 1987], as well as coupling of the stratosphere to the troposphere [Black and McDaniel, 2007]. The predictability of these events was investigated in GloSea5, but not found to be highly significant. This is probably because the mean timing of the final warming is towards the end of the four month hindcast simulation (around 20th November at 10 hPa), and the final warming does not occur before the end of the hindcast for some ensemble members, thereby introducing a bias in the mean. It is likely that shorter lead-time forecasts would be required to produce skillful predictions of the final warming date.

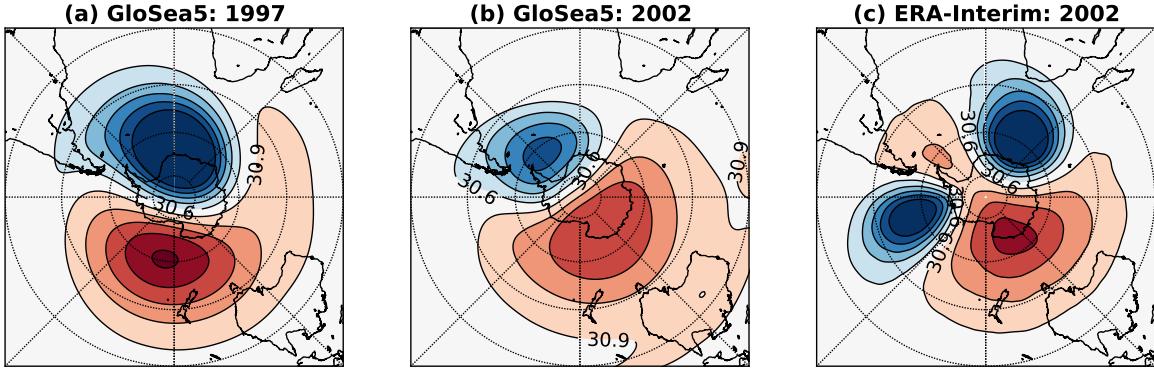

Figure 3.3: Geopotential height at 10 hPa at the central date (date at which \bar{U} at 60°S , 10 hPa is at its minimum value) of the two GloSea5 ensemble members which simulate a SSW (a,b), and for ERA-Interim at the central date of the 2002 SSW (c). Units are km and the contour interval is 0.3 km.

3.3.2 Ozone depletion

GloSea5 does not include interactive ozone chemistry, so in order to make ozone forecasts concentrations must be inferred from other meteorological variables. Total ozone quantities over the Antarctic polar cap have been found to be highly correlated with vertical EP flux poleward of 40°S [Weber *et al.*, 2011; Salby *et al.*, 2012]. This diagnostic is not likely to be produced directly by operational seasonal forecast systems and requires high frequency output at high spatial resolution to calculate. However, vertical EP flux dominates variability of the stratospheric polar vortex, so it may be possible to use the strength of the vortex to infer ozone quantities.

SON mean total column ozone quantities area-weighted averaged over the polar cap ($60\text{--}90^{\circ}\text{S}$) are shown in Fig. 3.4(a) for ERA-Interim and the Total Ozone Mapping Spectrometer (TOMS) satellite instrument [Kroon *et al.*, 2008]. ERA-Interim data are highly correlated with TOMS, verifying the accuracy of ERA-Interim against direct satellite measurements (TOMS values are slightly higher than ERA-Interim; this is probably because TOMS cannot make observations during the polar night). The long-term trend in polar cap total column ozone is calculated by fitting a second-order polynomial to the data. This long-term trend is due to changes in concentrations of CFCs and other ozone-depleting substances, and largely unrelated to dynamical variability. On the other hand, shorter-term interannual changes are strongly related to dynamical variability. In Fig. 3.4(b) anomalies of polar cap total column ozone from the long-term trend are plotted

3.3. SEASONAL FORECAST RESULTS

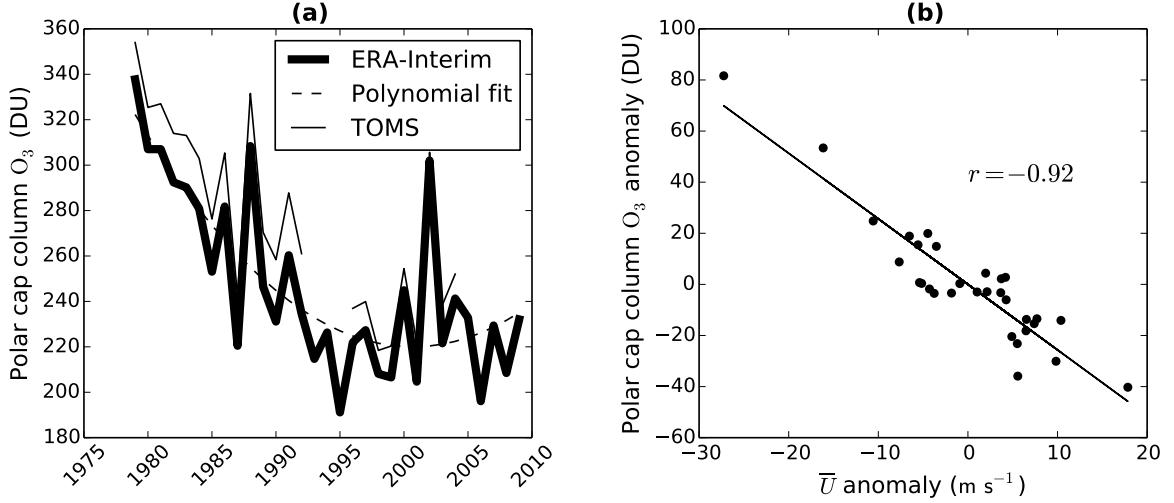

Figure 3.4: (a) Time series of SON mean polar cap averaged ($60\text{--}90^\circ\text{S}$) total column ozone in ERA-Interim and the TOMS satellite instrument. The ERA-Interim data are fitted with a 2nd-order polynomial. (b) Anomalies of ERA-Interim column ozone from the polynomial fit plotted against SON mean anomalies at 10 hPa and 60°S for each year from 1979–2009.

against anomalies of the SON mean \bar{U} at 60°S and 10 hPa. It can be seen that these two quantities are highly correlated ($r = -0.92$), meaning polar vortex variability explains approximately 85% of the variance of polar cap total column ozone anomalies.

This observed correlation can be used with the GloSea5 forecasts of polar vortex winds to produce inferred predictions of polar cap total column ozone quantities. Figure 3.2(b) shows the GloSea5 hindcasts along with the assimilated values from ERA-Interim. The correlation between the GloSea5 ensemble mean and ERA-Interim is 0.72, which is statistically significant at the 99% level. Errors from the regression in Fig. 3.2(b) for the inferred ozone quantities for each ensemble member are small compared to the spread between ensemble members, and so not plotted in this figure.

3.3.3 Southern Annular Mode

The SAM index in both GloSea5 and ERA-Interim is depicted as the difference between the normalized anomalies of zonally averaged mean sea-level pressure at 40°S and 65°S [Gong and Wang, 1999]. These anomalies are calculated from the respective climatologies of GloSea5 and ERA-Interim. The ERA-Interim SAM index calculated in this way is also highly correlated with other measures of the SAM, such as the station-based index of Marshall [2003]. The GloSea5 hindcast

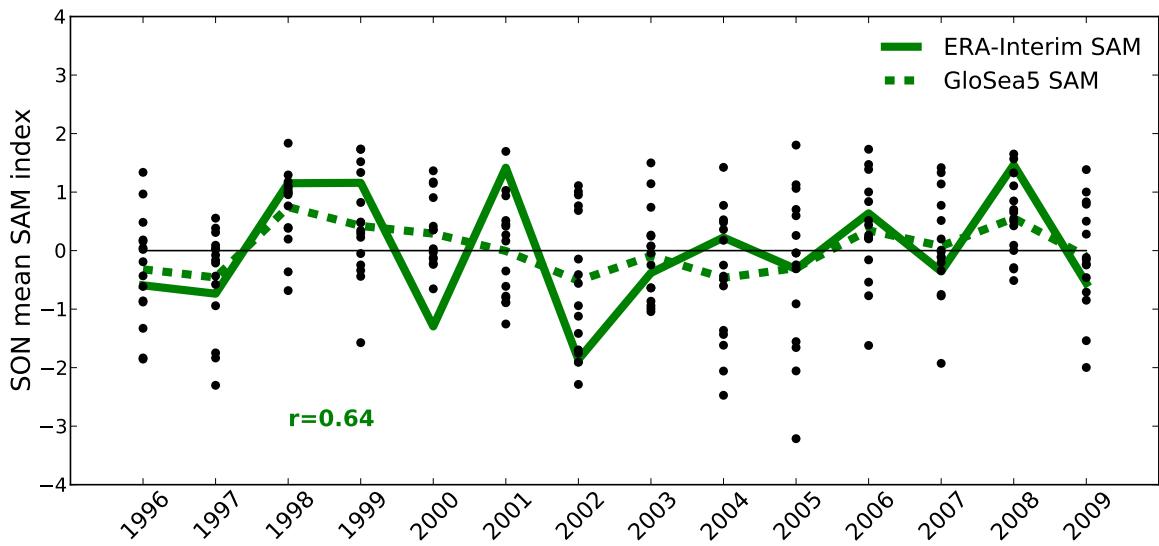

Figure 3.5: SON mean Southern Annular Mode (SAM) index in individual GloSea5 hindcast ensemble members (dots), ensemble mean (dashed green curve) and ERA-Interim (solid green curve). The SAM is calculated from mean sea-level pressure data, and hindcasts initialised near 1st August. The correlation of the ensemble mean and ERA-Interim values is 0.64, which is statistically significant at the 99% level.

skill for the prediction of the seasonal (SON) mean SAM index is shown in Fig. 3.5. The correlation of the GloSea5 ensemble mean and ERA-Interim is 0.64, which is statistically significant at the 99% level, confirming skillful prediction of the SAM at 1–4 month lead times. This is similar to the value for the NAO correlation skill of 0.62 found by *Scaife et al. [2014]* in the same seasonal forecast system.

Figure 3.6(a) shows the correlation of ERA-Interim and GloSea5 SON averaged mean sea-level pressure anomalies at each grid point in the Southern Hemisphere. As would be expected from the low frequency variability of ENSO, correlations are greatest over the tropical Pacific. However, the correlations are also as high as 0.7 across southern Australia and parts of Antarctica. On the other hand, correlations over southern Africa and South America are not found to be significant. It is perhaps unsurprising that there is little skill over the Andes region, since this is significantly above sea-level, so mean sea-level pressure is not well defined.

Correlations of GloSea5 SON average near-surface temperature with the gridded station-based data set HadCRUT4 [*Morice et al., 2012*] are shown in Fig. 3.6(b). This dataset is chosen because of the scarcity of temperature observations in the Southern Hemisphere, which introduces significant biases into reanalysis data. Again, the highest correlations are found near the tropical Pacific, but significant correlations of about 0.5 are found across eastern Australia, New Zealand and

3.3. SEASONAL FORECAST RESULTS

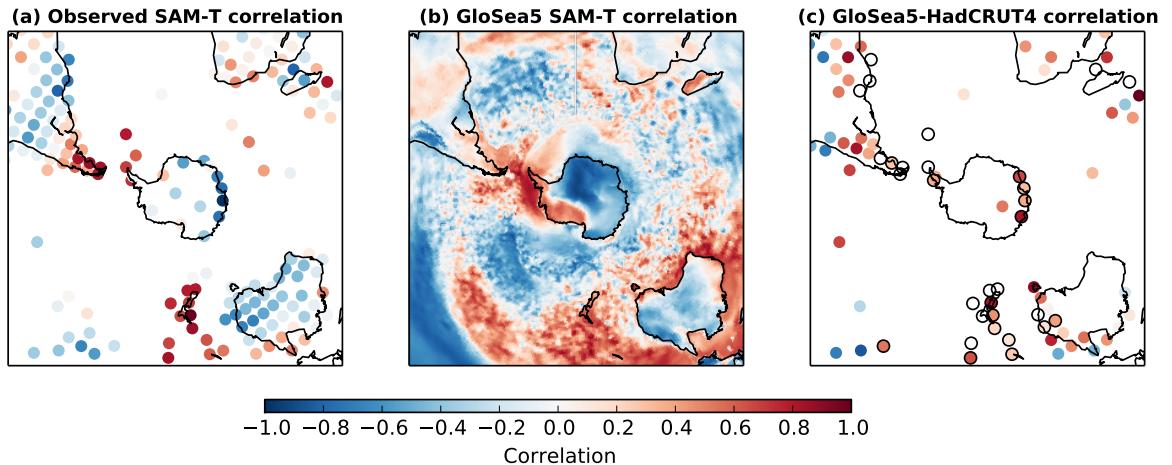

Figure 3.6: (a) Correlation of SON mean sea-level pressure in the GloSea5 ensemble mean with ERA-Interim values. (b) Correlation of SON mean near-surface air temperature in the GloSea5 ensemble mean and HadCRUT4 gridded station-based temperature data. Regions with no observations are white and grey shading indicates regions where the correlation is not greater than zero at the 95% confidence level, using a bootstrap test at each gridpoint.

Antarctica. There are also significant correlations in southern Africa and South America. The extratropical regions where the greatest forecast skill is found are similar to those which are observed to be most affected by variations in the SAM [Gillett *et al.*, 2006].

3.3.4 Stratosphere-troposphere coupling

Given that statistically significant skill in hindcasts of the stratospheric polar vortex is found at the same time of year as skill in predictions of the SAM, the question arises as to whether skill in one may affect the other. In order to investigate this, forecast skill as a function of lead-time and height is studied for polar cap ($60\text{--}90^{\circ}\text{S}$) mean geopotential height anomalies (Z')¹. Figure 3.7(a) shows the correlation of Z' in ERA-Interim with the GloSea5 ensemble mean hindcast values. Values are smoothed with a 30-day running mean before correlations are calculated, and plotted such that values for 15th September represent the correlation of the ERA-Interim and GloSea5 ensemble mean September mean values (without this smoothing, there are noisier but still significant correlations in a similar pattern).

¹At 1000 hPa monthly mean Z' is highly correlated ($r = 0.98$) with the SAM index

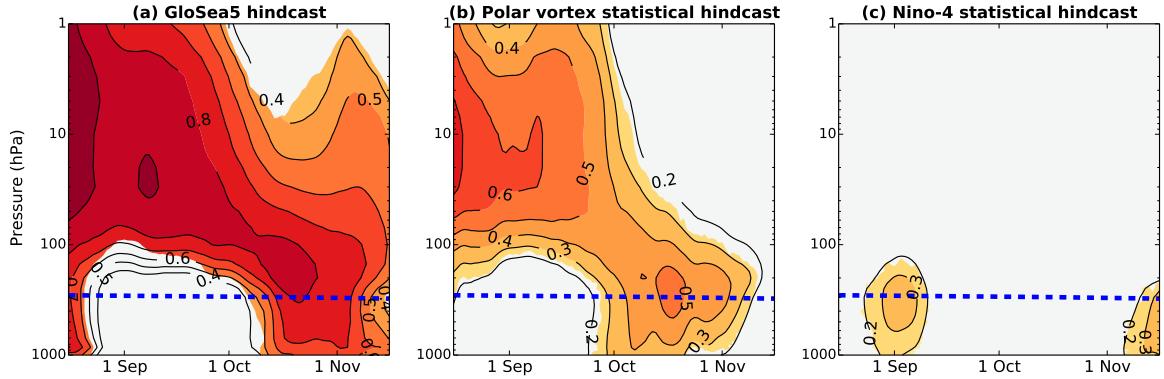

Figure 3.7: (a) Correlation of GloSea5 ensemble mean polar cap ($60\text{--}90^{\circ}\text{S}$) geopotential height anomalies (Z') with ERA-Interim values from 1996–2009, as a function of time and height. (b) Correlation of ERA-Interim from 1979–2010 values with those predicted by a linear statistical model based on Z' at 10 hPa on 1st August. All values are smoothed with a 30-day running mean before correlations are calculated. The contour interval is 0.1 and all colored regions are greater than zero at the 95% confidence interval, using a bootstrap test at each time at height. The blue dashed line indicates the approximate polar cap mean tropopause level [Wilcox *et al.*, 2012].

As would be expected from the initialisation of GloSea5 from ERA-Interim data, correlations are high in both the troposphere and the stratosphere for the August mean, due to predictability on weather timescales. However, tropospheric and lower-stratospheric skill rapidly decays and becomes statistically insignificant throughout September. In contrast, stratospheric correlations remain statistically significant throughout the hindcast simulation, and as high as 0.8 through to mid-October (corresponding to a 2–3 month lead time). This observed greater stratospheric than tropospheric skill might be expected from the longer ‘memory’ of the stratosphere; SAM decorrelation timescales are about 60–70 days in the stratosphere but only about 10 days in the troposphere during SON [Simpson *et al.*, 2011].

Importantly, the region of high levels of stratospheric skill descends with time and is present at the tropopause at the same time as a re-emergence of significant tropospheric skill in mid-October. This re-emergence cannot be accounted for by the persistence of tropospheric anomalies, so must be the result of the effect of another predictable signal on the tropospheric circulation. An obvious candidate for such a signal is the polar stratosphere, since this remains predictable throughout the hindcast period. The re-emergence of tropospheric skill also occurs at the same time as the strongest observed coupling between the stratosphere and troposphere found in other studies [e.g., Thompson *et al.*, 2005; Simpson *et al.*, 2011].

3.4. DISCUSSION

In order to determine the stratospheric influence on tropospheric skill, a simple statistical forecast model is formed, which has as its only input the initial conditions of the Antarctic stratosphere. ERA-Interim values are used to produce this model based on the linear regression of Z' at 10 hPa on 1st August with Z' at all other times and heights for 31 of the 32 years from 1979–2009. This model is then used to produce a hindcast of the 32nd year based on its Z' at 10 hPa on 1st August. The method ensures that no information from the hindcast year enters the model. The process is then repeated to make hindcasts of all 32 years; a procedure known as leave-one-out cross validation [Wilks, 2006].

Figure 3.7(b) shows the average correlation of 30-day running means of these statistical forecasts with ERA-Interim values. As might be expected, skill is initially high in the mid-stratosphere but not the troposphere. As with the GloSea5 hindcasts, the region of high skill descends with time, and statistically significant correlations re-emerge in the troposphere throughout October. This demonstrates that skilful forecasts of the Antarctic troposphere during October can be produced based only on knowledge of Z' in the mid-stratosphere on 1st August. It also suggests that the re-emergence of tropospheric skill in the GloSea5 hindcasts in October is likely to be caused by persistent stratospheric anomalies which descend with time.

The statistical hindcasts in Fig. 3.7(b) show lower skill than the GloSea5 hindcasts at all times, and do not show statistically significant tropospheric correlations, nor the increase in upper-stratospheric skill during November. These observations could potentially be explained by the importance of non-linearities or the influence of external factors, such as ENSO, on the Antarctic stratosphere-troposphere system. Indeed, statistical hindcasts similar to those shown in Fig. 3.7(b) were produced based on the Niño-3 index, and found to have statistically significant tropospheric skill during November, but none at other times or heights. This is consistent with the results of Lim *et al.* [2013], who find the greatest correlation between tropical Pacific sea-surface temperatures and the SAM during November–January.

3.4 Discussion

We have demonstrated that Antarctic total column ozone amounts are predictable up to four months in advance during the austral spring, even with a model which

lacks interactive chemistry. While using such a model has the advantage of being less computationally expensive than a chemistry-climate model, there are also some drawbacks. Primarily, the model will not be able to simulate zonal asymmetries in ozone concentrations or the feedback between ozone concentrations and stratospheric temperatures. Both these factors have been shown to be important in driving long-term trends in the SAM as a result of ozone depletion [Thompson and Solomon, 2002; Crook *et al.*, 2008; Waugh *et al.*, 2009].

Perhaps more relevant for seasonal forecasts is the fact that we have not been able to determine whether the observed strong correlation between the stratospheric circulation and Antarctic ozone concentrations is dominated by a chemical or dynamical mechanism. If the relationship is dominated by a chemical mechanism, whereby enhanced descent over the pole inhibits the activation of ozone-depleting substances, we would expect the correlation to weaken as concentrations of these substances return to pre-industrial levels. Accurate forecasts of ozone with models lacking interactive chemistry would then not be possible. On the other hand, if the mechanism is largely dynamical, whereby transport of ozone-rich air from the tropics is the important factor, we would not expect the relationship to change in time. Although a study to distinguish these mechanisms has been carried out for chemistry-climate models [Garny *et al.*, 2011], it has not been possible to do so in observations. In either case, we do not expect the relationship to break down soon, as concentrations of ozone-depleting substances are not projected to return to 1980 levels until the late 21st century [WMO, 2011].

The correlation skill of 0.64 for the SON mean SAM in the GloSea5 hindcasts is greater than that of other contemporary seasonal forecast systems at similar lead times. For instance, Lim *et al.* [2013] report a correlation of 0.3–0.4 for the SON mean SAM from 1st August initialised forecasts using the Predictive Ocean and Atmosphere Model for Australia, version 2 (POAMA2). Significantly, this system has only two model levels in the stratosphere, and so is unable to simulate the stratosphere-troposphere coupling described here. Lim *et al.* [2013] suggest that the significant SAM predictability found from October–January in their system is the result of the influence of ENSO through a tropospheric teleconnection. These findings are not inconsistent with our results, since this time period is beyond the extent of the GloSea5 hindcasts, and largely after the stratospheric final warming, when the stratosphere is much less variable. Lim *et al.* [2013] were also mostly concerned with longer range forecasts (up to 6-month lead time) which are be-

3.4. DISCUSSION

yond the persistence time scales of the Antarctic stratosphere, but within those of the tropical Pacific.

Despite this significant correlation skill in hindcasts of the SAM, it is clear from 3.5 that the amplitude of the ensemble mean hindcast is much less than that of observations. The signal-to-noise ratio (ratio of the standard deviation of the ensemble mean to that of all ensemble members) is just 0.4. For a ‘perfect’ forecast system (one in which observations are indistinguishable from an ensemble member), the signal-to-noise ratio and correlation are directly related [Kumar, 2009], so that the expected correlation would be just 0.3. The fact that it is greater than this is because the average correlation between ensemble members and observations is much greater than that between pairs of ensemble members. A similar but smaller difference is also found for the stratospheric polar vortex forecasts. These results mean that individual ensemble members have a smaller predictable signal than observations.

Given this result, it might be expected that more skillful predictions could be obtained with a larger ensemble size. To illustrate the variation of hindcast skill with ensemble size we systematically sample smaller sets of forecasts from the full 15 members for each year, following the method of *Scaife et al.* [2014]. This is repeated many times and an average value for a given sample size calculated. This variation of correlation skill with ensemble size for both the SON mean SAM and stratospheric polar vortex winds is shown in Fig. 3.8. These curves closely follow the theoretical relationship of *Murphy* [1990], which relies only on the mean correlation between pairs of ensemble members, $\langle r_{mm} \rangle$, and the mean correlation between individual ensemble members and observations, $\langle r_{mo} \rangle$, given by

$$r = \frac{\langle r_{mo} \rangle \sqrt{n}}{\sqrt{1 + (n - 1)\langle r_{mm} \rangle}} \quad (3.1)$$

where r is the ensemble mean correlation, and n is the ensemble size. These curves are shown in Fig. 3.8, along with their asymptote for an infinite sized ensemble. Although the stratospheric forecasts cannot be greatly improved with a larger ensemble size in the current system, correlation scores of about 0.7 of the SAM could be achieved with an ensemble size near 30. Both have an asymptote near 0.8, similar to that found by *Scaife et al.* [2014] for the NAO.

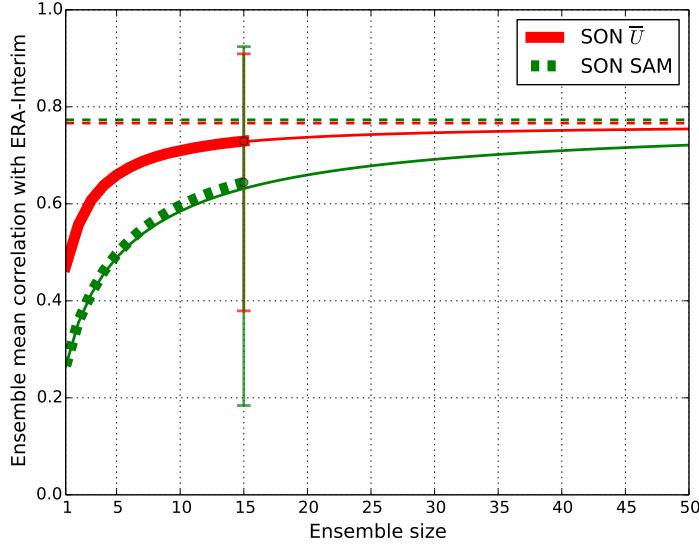

Figure 3.8: GloSea5 ensemble mean correlation with ERA-Interim as a function of ensemble size for the SON mean \bar{U} at 10 hPa and 60°S and SON mean SAM (thick lines). A theoretical estimate of the variation of correlation with ensemble size is shown in each case (thin solid lines), along with its asymptote for an infinite sized ensemble (dashed lines)

3.5 Conclusions

Using a set of seasonal hindcasts initialised at the start of the austral spring, we have demonstrated skillful prediction of the interannual variability of the Antarctic stratospheric polar vortex at 1-4 month lead times. This includes extreme events such as the 2002 SSW, which is the most extreme year in the ensemble mean, and has one ensemble member which simulates a SSW. Because this variability is observed to be closely correlated with Antarctic column ozone amounts, we are able to infer skillful prediction of interannual variability in Antarctic ozone depletion.

We also find significant skill, which exceeds that of other contemporary seasonal forecast systems, in hindcasts of the spring mean SAM index. By studying the variation of this skill with time and height, we suggest that this skill is influenced by stratospheric anomalies which descend with time and are coupled with the troposphere in October and November. In fact, the influence of the stratosphere is such that skillful statistical predictions of the October SAM can be made using only information from 1st August in the mid-stratosphere.

Assuming that the 14 year period studied here is representative of future years, these results suggest that it may now be possible to make skillful seasonal forecasts of interannual variations in ozone depletion and large scale weather patterns

3.5. CONCLUSIONS

across the Southern Hemisphere. They also demonstrate the importance of the inclusion of a well-resolved stratosphere in seasonal forecast models.

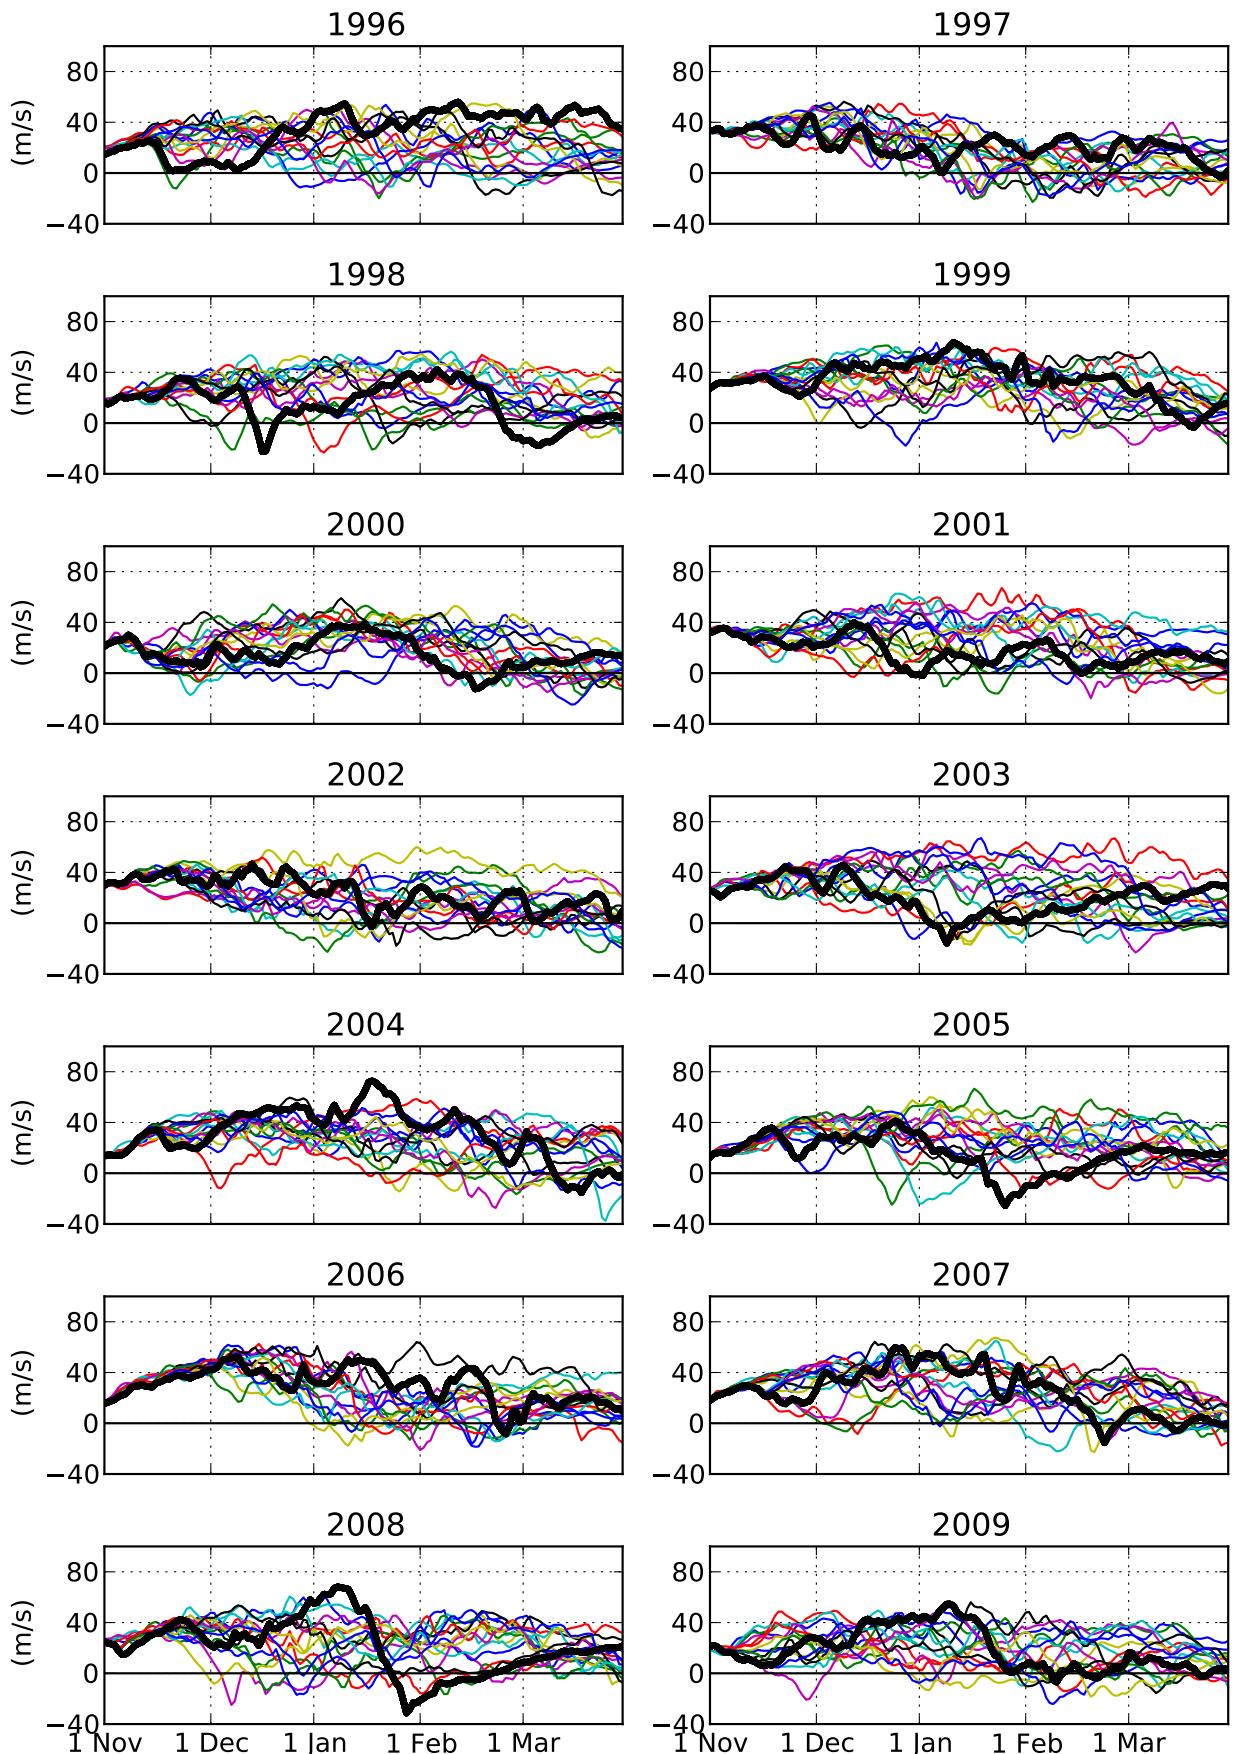

Figure 3.9: Timeseries of zonal-mean zonal wind in the Arctic polar vortex (60°N , 10 hPa) in the ERA-Interim reanalysis (thick black lines) and the GloSea5 ensemble hindcasts (thin coloured lines). Individual ensemble members are initialised from dates centred on November 1st.

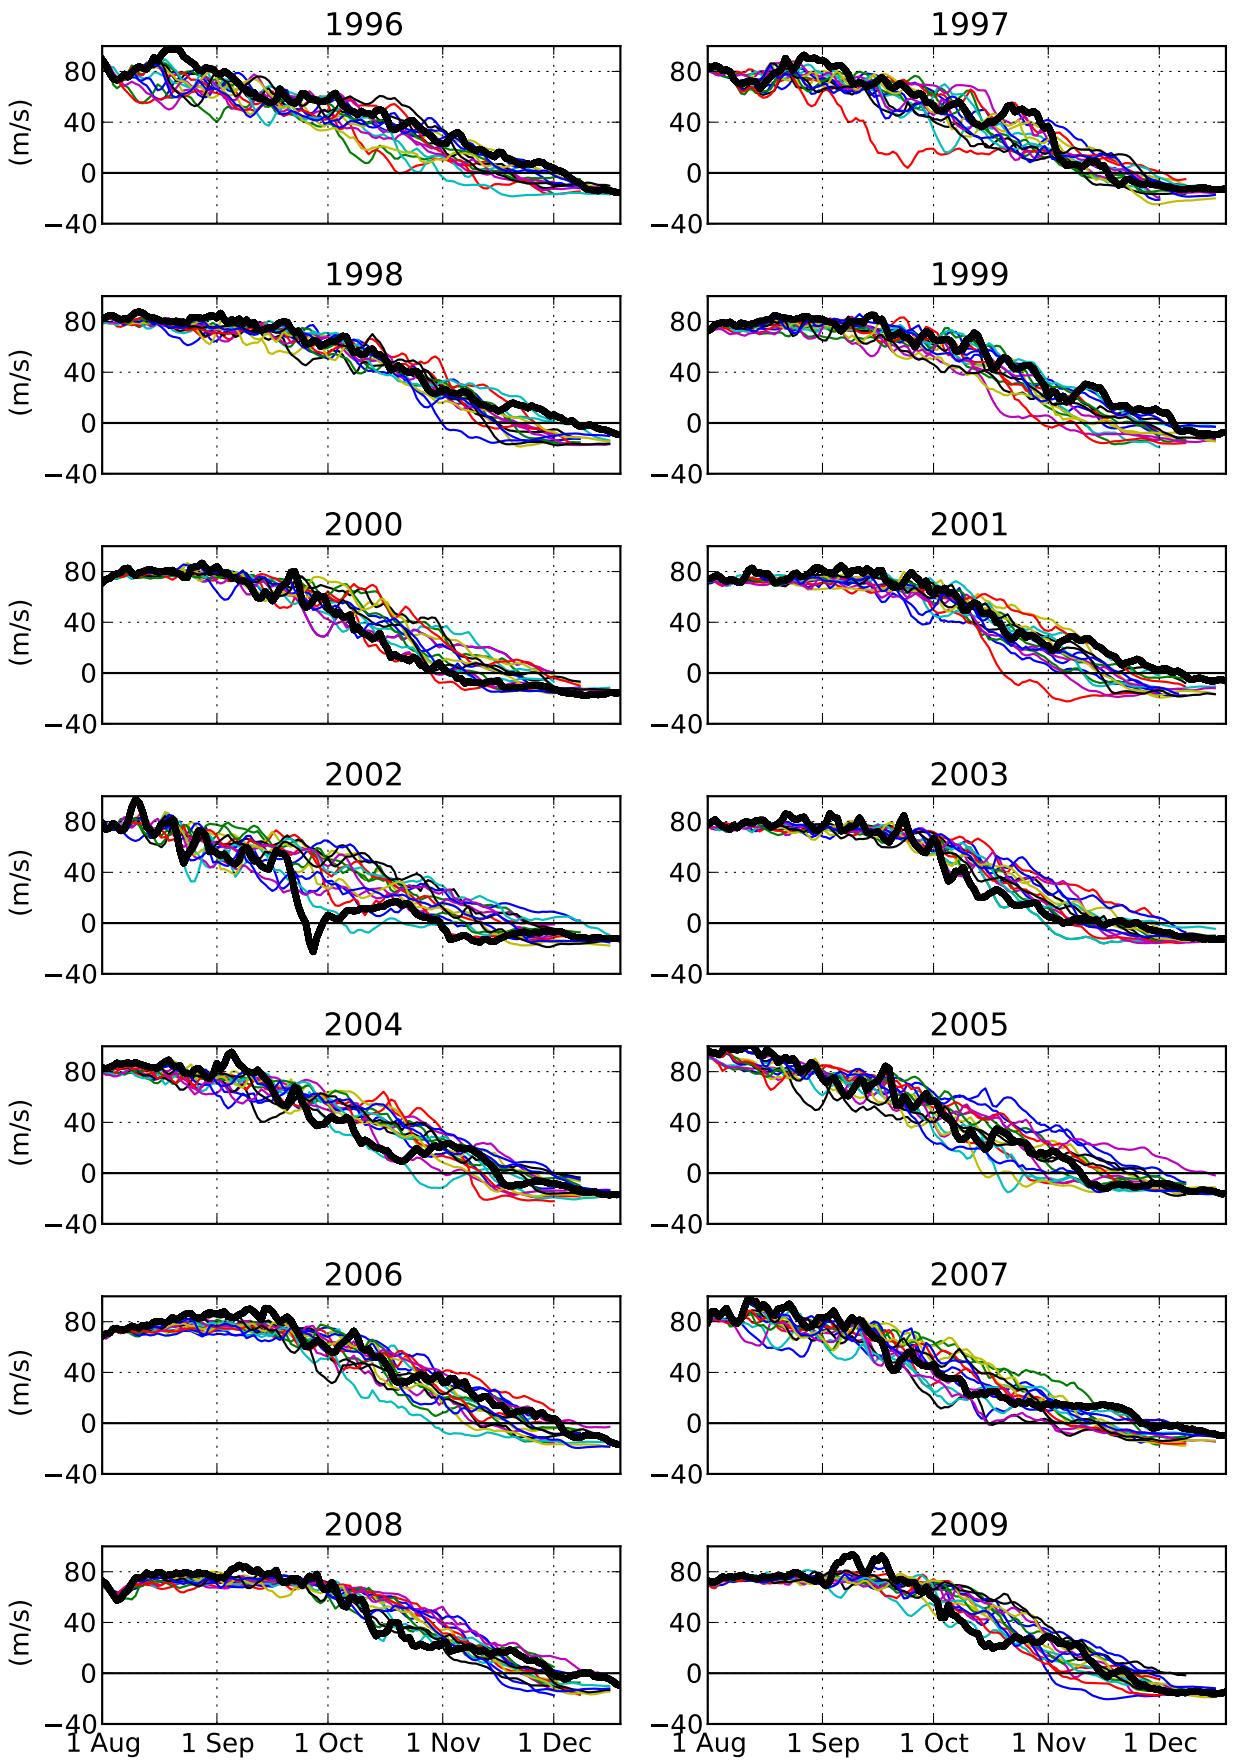

Figure 3.10: As figure 3.9 but for the zonal-mean zonal wind in the Antarctic polar vortex (60°S , 10 hPa), and ensemble members initialised from dates centred on August 1st.

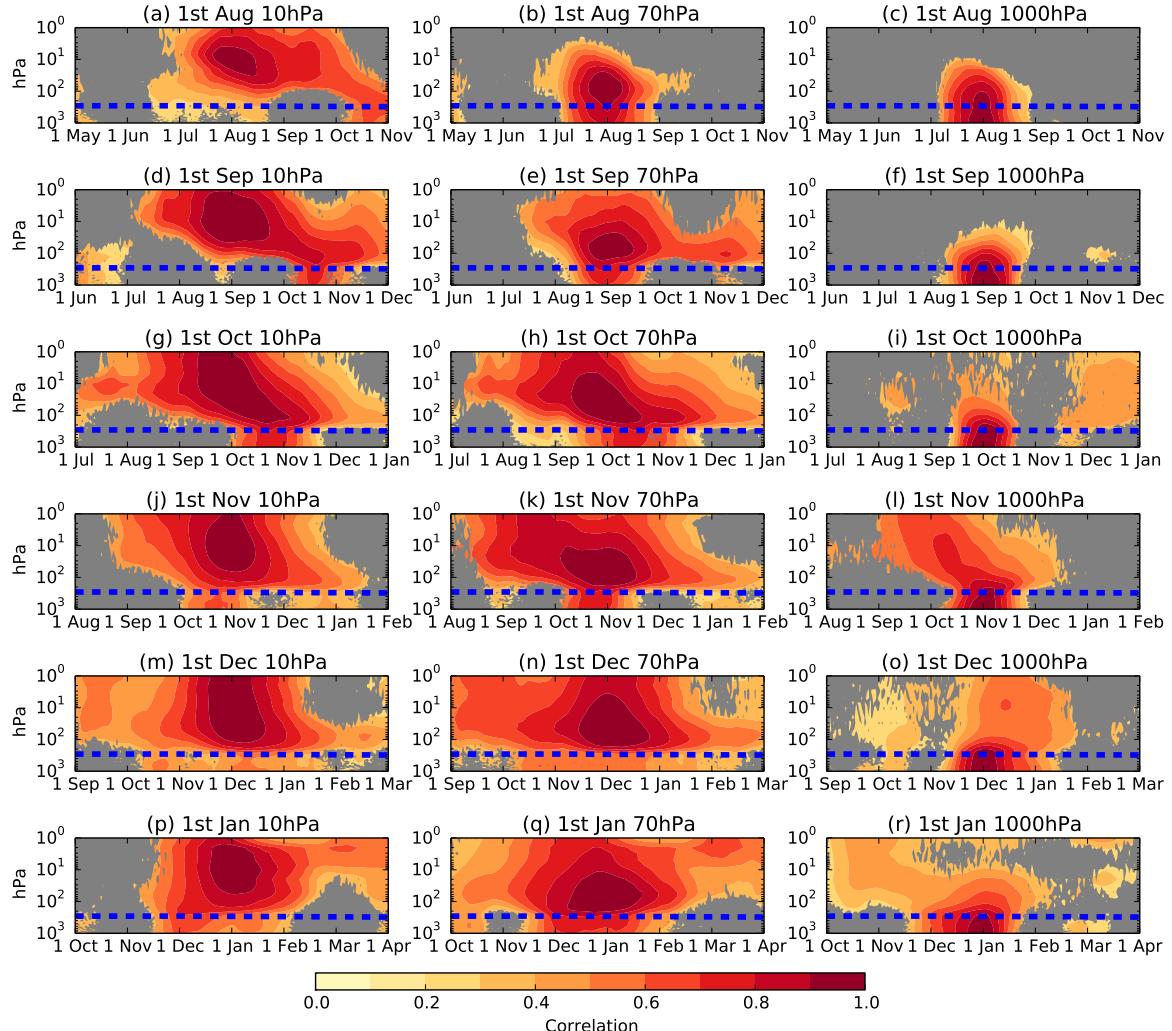

Figure 3.11: Correlation of ERA-Interim (1979–2010) Z' at 10 hPa, 70 hPa, and 1000 hPa with Z' at other times and lags. Values are smoothed with a 30-day running mean before correlations are calculated, and colours represent correlations that are 95% significant from zero according to a bootstrap test.

3.5. CONCLUSIONS

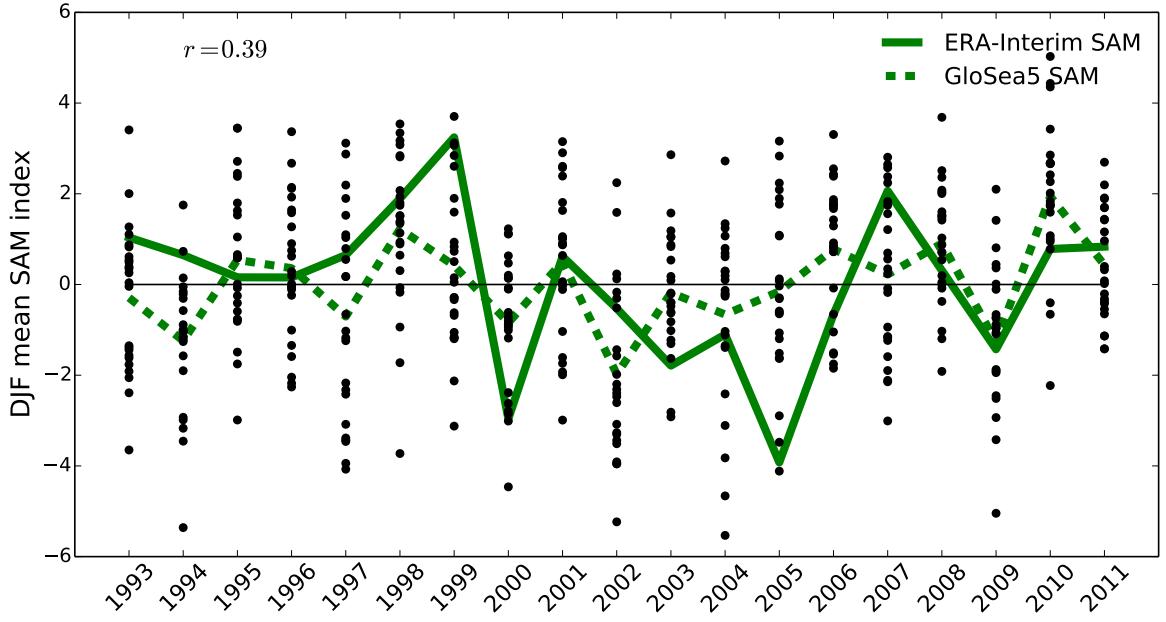

Figure 3.12: DJF mean Southern Annular Mode (SAM) index in individual GloSea5 hindcast ensemble members (dots), ensemble mean (dashed green curve) and ERA-Interim (solid green curve). The SAM is calculated from mean sea-level pressure data, and hindcasts initialised near 1st November. The correlation of the ensemble mean and ERA-Interim values is 0.39

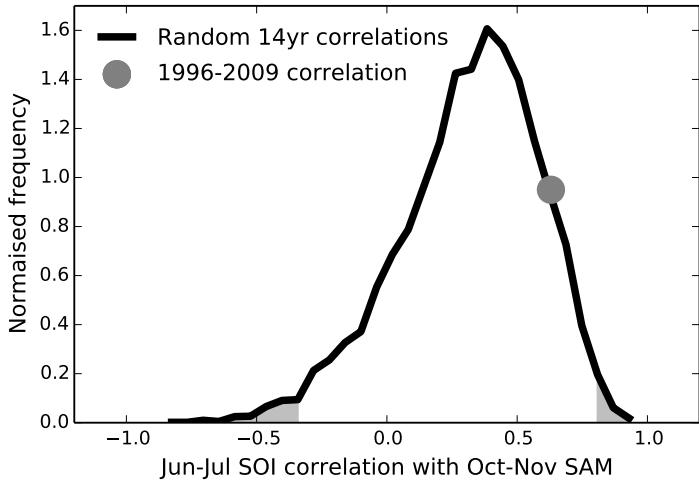

Figure 3.13: Histogram of correlations of random 14-year samples of detrended June–July SOI with October–November SAM. Also shown is the correlation over the 1996–2009 hindcast period. Grey shading indicates the < 2.5% and > 97.5% ranges.

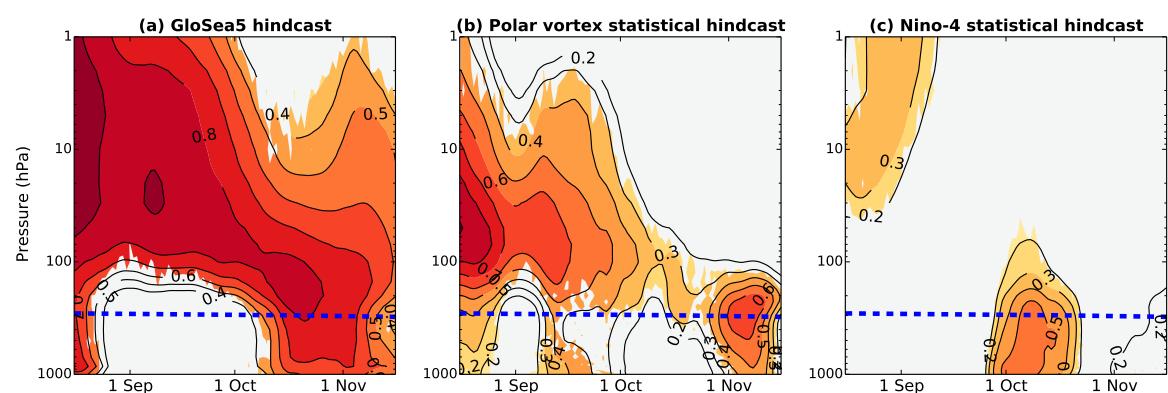

Figure 3.14: As Figure 3.7 but all analysis restricted to the 1996–2009 period.
